The same visceral changes often occur in different emotional states and in non-emotional states. Recall that the arousal associated with emotions arises from the sympathetic nervous system. Cannon argued that, because the activity of the sympathetic nervous system is typically general and non-specific, several emotions probably share similar patterns of visceral activity. Cannon further noted that certain non-emotional events, such as fever, produce patterns of sympathetic nervous system activity that are similar to the patterns that accompany emotions, although they are not experienced as emotions.

The viscera are rather insensitive structures. According to Cannon, "We can feel the thumping of the heart because it presses against the chest wall, we can also feel the throbbing of the blood vessels because they pass through tissues well supplied with sensory nerves . . . [but], normally, the visceral processes are extraordinarily undemonstrative" (1927, p. 111).

Visceral changes are too slow to be the source of emotional feeling. Cannon argued that the amount of time it takes for the body's vasomotor system to communicate with the brain and send impulses back to the rest of the body is too slow "to be the occasion for the appearance of affective states" (1927, p. 112).

Artificially inducing visceral changes does not produce strong emotions. Citing research by Spanish psychologist Gregorio Marañon (1924), Cannon pointed out that the injection of adrenalin, a stimulant, into the bloodstream of research participants, which activates the sympathetic nervous system and produces visceral changes characteristic of intense emotions, does not lead to discrete and identifiable emotional reactions.

Following his critique of the James-Lange theory, Cannon (1927) offered his own explanation of emotion, which was later elaborated on by Philip Bard (1934). This theory, often referred to as the **Cannon-Bard theory of emotion**, states that when we perceive an emotionally stirring event, the *thalamus*, a key brain structure, simultaneously relays information about the event to both the sympathetic nervous system and to the parts of the brain that are active in thought and decision making. As a result, the subjective experience of emotion and the activation of the sympathetic nervous system (that is, bodily arousal) occur simultaneously (see Figure 11.11 again).

Cannon-Bard theory of emotion a theory proposing that the subjective experience of emotion and the activation of the sympathetic nervous system (that is, bodily arousal) occur simultaneously.

Schachter and Singer's Two-Factor Theory

In 1962, Stanley Schachter and Jerome Singer, American social psychologists, published a

landmark study that helped change psychology's understanding of emotion. According to Schachter and Singer (1962), earlier theories had neglected to consider the influence of cognition, or thought processes, in our emotional experiences. Physiological differences alone are too subtle to define specific emotional states, said these researchers; it is our cognitive appraisal of the immediate situation that provides a label ("I am afraid") for our bodily feelings.

Agencja Fotograficzna Caro/Alamy Stock Photo

Theories of emotion **The timing of and relationships among the situations we find ourselves in, our internal physiological arousal, and our interpretations of what our circumstances mean to us are all part of the various theories of emotion. While no child likes getting shots, how intensely he or she responds can vary by age and culture.**

According to **Schachter and Singer's two-factor theory of emotion**, "It is the cognition which determines whether the state of physiological arousal will be labeled as 'anger,' 'joy,' 'fear,' or 'whatever'" (Schachter & Singer, 1962, p. 380). Schachter and Singer suggested that, although physiological arousal is *necessary* for an emotion to occur—in fact it determines the intensity of the emotional experience—it's up to our cognitive faculties to determine our specific emotional state (see Figure 11.11).

Schachter and Singer's two-factor theory of emotion a theory proposing that an emotional state is a function of both physiological arousal and cognition.

If we were to apply Schachter and Singer's two-factor theory to the situation of a child receiving a shot, we would assume that the severity of the child's actions was determined by his level of physiological arousal. If his arousal had been mild or moderate, he might have appraised the situation differently ("This is not so bad") and might have responded in a mildly fearful or stressful way (making a face or saying "ouch"). If instead he experienced intense physiological arousal and appraised the situation in a way that led to terror ("This is going to be unbearable"), this would make him respond in ways that ultimately make the situation much more difficult (see photo).

Schachter and Singer's two-factor theory also suggests that, when the cause of our physical arousal is not immediately clear to us, we use cues from our surroundings to help us identify a cause. This can lead to mislabelling physical arousal from a non-emotional source as an emotion. Schacter and Singer (1962) conducted a well-known experiment at the University of Minnesota to test this idea (see **Figure 11.12**). They told undergraduate research participants that the study was examining the effects of a vitamin supplement (they called it *Suproxin*) on vision.

When the students arrived at the lab, they were met by an experimenter and told that they would be receiving a small injection of Suproxin and then would complete several vision tests. The participants received an injection of either epinephrine (adrenalin) or a placebo (saline solution). By producing physiological arousal, the epinephrine injections mimicked sympathetic nervous system activation. Among those who received epinephrine, one-third (the *informed group*) were told they might experience side effects, such as palpitations, trembling, and facial flushing; one-third (the *deceived group*) were told they would experience no side effects; and one-third (the *misinformed group*) were told they would experience side effects that were not in fact likely to occur, such as headaches. All the participants in the placebo group were told they would have no side effects from their injections. After the participants were given the drug, a confederate of the experimenters' entered the room and acted either euphoric or angry. These manipulations allowed Schachter and Singer to create a scenario in which participants experienced bodily arousal either with or without plausible explanations for it.

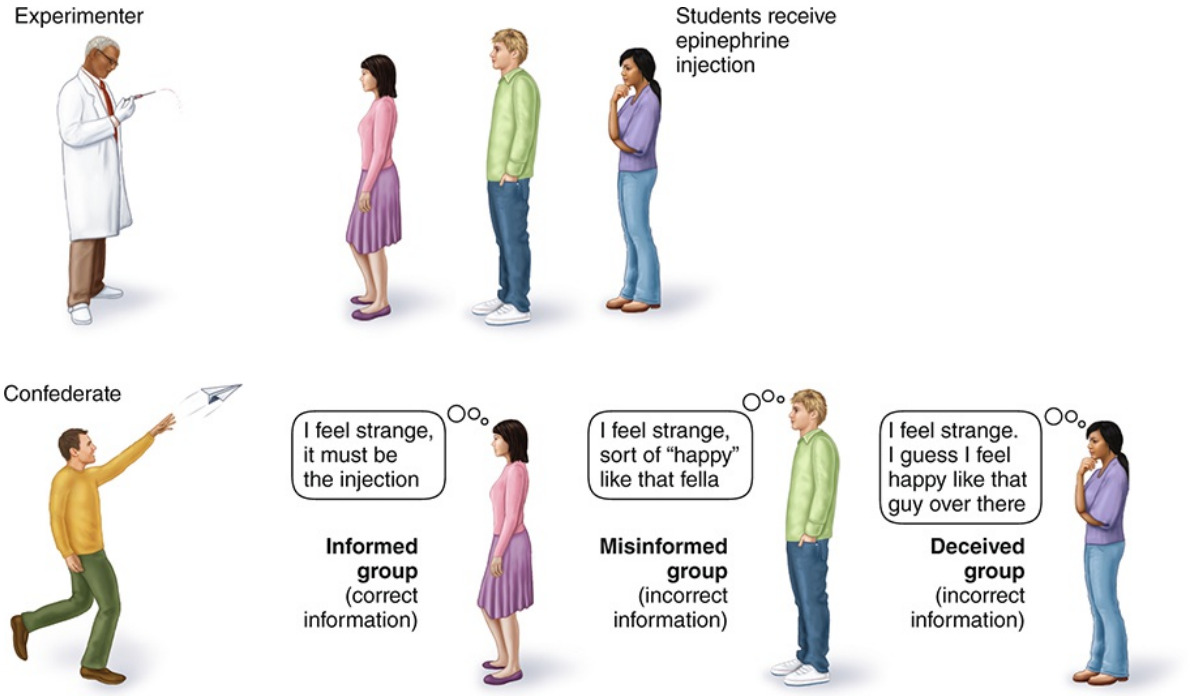

FIGURE 11.12 Testing the two-factor theory In the absence of correct information, participants in the deceived and misinformed groups who received the epinephrine injection concluded that they were feeling happy, like the confederate who had acted euphoric.

As Schachter and Singer's two-factor theory had predicted, students who received an epinephrine injection but were not given a proper explanation for their bodily arousal (the deceived and misinformed groups) later reported feelings of anger or euphoria when they encountered an angry or euphoric confederate (acting that way on the instructions of the experimenter). In contrast, students in the epinephrine condition who were told to anticipate various symptoms of sympathetic nervous system activity (informed group) did not experience anger or euphoria—they were immune to any effects of the arousal manipulation. Clearly, the label of an emotion is influenced by whether or not a person has an appropriate explanation for the arousal.

Schachter and Singer's two-factor theory served to redirect the focus of emotion research toward the role of cognitive factors. Indeed, a number of studies have since provided indirect evidence for their two-factor theory. In a classic study conducted by Don Dutton of the University of British Columbia, for example, male participants were approached by an attractive female (a confederate of the researchers) and asked to complete questionnaires. Males approached by the woman while crossing the Capilano Suspension Bridge in British Columbia—a long, narrow footbridge constructed of wooden boards and wire cables suspended about 30 metres (100 feet) above a river and near very dramatic falls—later reported being more attracted to the female confederate than males who met the same woman on a wider, sturdier bridge only about 3 metres (10 feet) above the river (Dutton & Aron, 1974). The researchers concluded that the men on the shaky Capilano Bridge had experienced anxious arousal because of the height of the bridge and had misinterpreted this arousal as sexual attraction—findings consistent with Schachter and Singer's two-factor theory (see photos).

Echoes of the Capilano Bridge study **The couple on the left pose for wedding pictures on the Capilano Suspension Bridge in North Vancouver. This wooden-**

boarded, not-so-sturdy footbridge stands high above the water and near the sounds of water pouring over the top of the Capilano dam. If asked, they might well talk more about their strong feelings for each other rather than any fear induced by the swaying bridge and sounds of rushing water. What about the couple on the right on their much lower, less threatening bridge?

Cognitive-Mediational Theory

One theory that built on Schachter and Singer's ideas was developed by Richard Lazarus, an influential psychologist at the University of California, Berkeley. Lazarus spent much of his career investigating the role of appraisal in people's reactions to stress (Lazarus, 2007; Lazarus et al., 1965; Lazarus & Alfert, 1964). Eventually, Lazarus came to believe that appraisal must play a similar role in emotional experiences to that which it plays in stress reactions. Unlike Schachter and Singer's two-factor theory, Lazarus's theory holds that appraisal affects not only how people interpret physical arousal, but also the level of arousal itself. As such, the **cognitive-mediational theory of emotion** views cognitive interpretations of events as playing a still broader role in the experience of emotion.

> **cognitive-mediational theory of emotion** a theory proposing that cognitive interpretations, particularly appraisals, of events are the keys to experiences of emotion.

In one of his early studies, for example, Lazarus and his colleagues had participants watch stressful films (featuring, for example, skin-piercing rituals among Australian tribesmen) while their autonomic nervous system activity was measured and their subjective reports of stress were recorded. Some of the viewers were told "the people in this film were not hurt or distressed by what is happening," while others were told, "many of the people you see in this film suffered severe pain and infection from these rituals." By influencing the way the participants construed what was happening in the films, Lazarus and his colleagues found they could greatly alter the participants' physiological activity and subjective stress reactions while viewing. That is, appraisal serves as a *cognitive mediator* between environmental stimuli and people's reaction to those stimuli (Biggs, Brough, & Drummond, 2017; Lazarus, 2007, 1993a, 1993b).

Facial-Feedback Theory

We mentioned earlier, in discussing the behavioural component of emotion, that people may begin to experience an emotion just by pretending to express it. Related to this observation is the **facial-feedback theory of emotion**, which is derived from Charles Darwin's early (1872) notion that muscular activity can either strengthen or lessen the experience of emotion. According to the current facial-feedback perspective, our subjective experiences of emotion are influenced by sensory feedback we receive from the activity of our facial muscles, our **facial efference** (Finzi & Rosenthal, 2016; Izard, 2007, 1997, 1977). Thus, facial expressions not only express a given emotion, but also intensify the physiological experience of that emotion.

> **facial-feedback theory of emotion** a theory proposing that subjective experiences of

emotion are influenced by sensory feedback from facial muscular activity, or facial efference.

facial efference sensory feedback from facial muscular activity.

In one study, for example, participants were directed to move their facial muscles into certain positions, without directly being told which emotions they were expressing. The facial changes produced significant changes in their autonomic nervous system arousal, as indicated by increases in their heart rates, skin conductance, and finger temperatures (Ekman, Levenson, & Friesen, 1983). In a related study, research participants held pens in their mouths while rating the funniness of cartoons (Strack, Martin, & Stepper, 1988). This approach enabled the experimenters to manipulate the participants' facial expressions without calling attention to their facial activity or to the emotions normally associated with that activity. People directed to hold the pen in their teeth made a face similar to a smile, while those directed to hold the pen with their lips were unable to smile (**Figure 11.13**). Sure enough, individuals who held the pen in their teeth found the cartoons funnier than those who held the pen in their lips. Check this out for yourself. Have several friends hold a pen in their lips for minutes and then ask them to rate their level of happiness on a 1 to 10 point scale. Have another group of friends hold a pen in their teeth for minutes and then rate their happiness on the same scale. Which group had the highest average happiness ratings?

The facial-feedback theory of emotion has also been supported by studies of the *Duchenne smile*, named after French neurologist Guillaume Duchenne. Duchenne observed that smiles reflecting genuine emotion involve the activity of certain muscles near the mouth and the eyes, whereas more artificial "social smiles" involve only muscles near the mouth (see **Figure 11.14**). One experiment found that participants who displayed genuine Duchenne smiles while viewing a positive film clip displayed greater physiological arousal and experienced more positive emotion than other participants (Krumhuber, Likowski, & Weyers, 2014). Apparently even preschool children expect more pro-social behaviour from people who display genuine (non-fake) smiles (Song, Over, & Carpenter, 2016).

How might facial expressions produce physiological arousal and the subjective experience of emotion? Several explanations have been proposed. It may be that facial expressions serve as *relays* between an emotionally stirring event and a resulting subjective experience of emotion. Indeed, psychologist Silvan Tomkins (1962) argued that emotionally stirring stimuli activate an inborn, almost reflexive "affect program" that sends signals throughout the body by motor and circulatory pathways, bypassing the parts of the brain involved in cognition. The body reacts to these signals in forms, such as facial expressions (smiles, frowns) and other activities, which then supply sensory feedback to the brain, producing the experience of an emotion. Tomkins (1992, 1980) further argued that receptors in the face change position when people contract their facial muscles and that this sensory information is also sent to the brain, ultimately leading to a felt emotion.

Mark Owens/John Wiley & Sons, Inc.

FIGURE 11.13 Testing the facial-feedback theory When you hold a pen between your teeth, you activate facial muscles that are associated with a smile and you are more likely to report pleasant feelings than if you held the pen between your lips (Strack, Martin, & Stepper, 1988).

Masterfile

Negative emotions While we may all recognize emotions such as sadness how the brain creates the behavioural expression of sadness may differ between individuals.

It is important to note that none of the theories just discussed seems to explain emotion completely. As psychologist Robert Zajonc has said, "It is unlikely that all emotions have the same etiology (see photo), are characterized by the same affective and cognitive processes, . . . or have the same underlying neuroanatomical structure and neurochemical actions" (Zajonc et al., 1989, p. 412). Thus, one emotional experience may result largely from a singular source, such as physiological arousal, cognitive appraisal, or facial expression, while others may be the product of a combination of these factors (Barrett, 2016; Cowen & Keltner, 2018; Kragel & LaBar, 2016).

Evolutionary Theory

In 1872, having noted the similarities in emotional expression across and within species throughout the world, Darwin published *The Expression of the Emotions in Man and Animals*. Here he argued that emotional expression in both people and animals serves a *communicative* function that is essential to survival. Emotional expressions may, for example, warn others of danger, dissuade enemies from attacking, or signal sexual receptiveness (LeDoux & Hoffman, 2018).

Evolutionary psychologists argue that certain emotions have been passed down through the generations because they have played an integral role in the survival of our species (Al-Shawaf, Conroy-Beam, Asao, & Buss, 2016; Cosmides & Tooby, 2013; Austad, 2020; Ketelaar, 2015). It may even be that each emotion corresponds to a particular situation that has occurred repeatedly throughout the course of evolution, and that each emotion increases an individual's ability to cope with the adaptive challenges that arise in such a situation (see **Table 11.3**). For example, organisms that experienced fear when confronted by predators most likely survived at a much higher rate than those that experienced calm during such interactions. Over time, as this situation was repeated, fear became a characteristic response to danger and, eventually, an innate, prewired, and automatic response. Such patterns of emotionality have been genetically passed on to us from generations of ancestors, making our lives much easier than if we were required to learn about every aspect of our environmental surroundings without their guidance.

Much of the research support for an evolutionary explanation of emotion centres on the universal and innate nature of facial expressions of emotion. As we observed earlier, Paul Ekman and his colleagues have conducted a series of studies on facial expressions of emotion (Cohn, Ambadar, & Ekman, 2007; Ekman, 2003; Ekman & Friesen, 1971). They found that individuals from many different cultural and language backgrounds, when presented with photographs of different facial expressions, are fairly accurate at selecting the emotions being expressed.

Based on such research on the universality of certain facial expressions and the evolution of emotion, a number of theorists have suggested that some innate, **basic emotions** are preprogrammed into all people, regardless of culture or country of origin, and have been shown to correspond to key areas of the brain (Saarimäki et al., 2016). Tomkins (1962) has proposed that there are eight basic emotions: surprise, interest, joy, rage, fear, disgust, shame, and anguish. Other notable theorists have proposed similar lists (Frijda, 1986). Indeed, it appears that infants typically display the facial expressions of such fundamental emotions very early in life (Izard, 1994). Even children who are born without sight display facial expressions similar to those of sighted children of the same age (Galati et al., 2003;

Goodenough, 1932).

basic emotions a group of emotions preprogrammed into all humans regardless of culture.

Situation	Emotion	Survival Function
Threat	Fear, terror, anxiety	Fight, flight
Obstacle	Anger, rage	Biting, hitting
Potential mate	Joy, ecstasy, excitement	Courtship, mating
Loss of valued person	Sadness, grief	Crying for help
Sudden novel object	Surprise	Stopping, attending

Emotions and the Brain

As you have read in the preceding sections, many factors influence our experience of emotions. These include our experiences, memories, and even our cultures. Many emotions can also be felt simultaneously. For example, most of us feel anger, sadness, and disgust when we see photos of elephants and rhinoceros that have been killed by poachers. These feelings have been coded into your brain via educational experiences and the memories we have created based on what we've learned about the detriments of poaching. In contrast, if you are a poacher, you may feel surprise and happiness when you find the animal you were looking for. Thus, our experiences and cognitions interact with our brain circuitry to create the emotions we "feel." While certain areas of the brain are important for the experience of emotion (see **Figure 11.15**), the wiring or circuitry between these structures is also critical for our experience of emotion (Hoemann, Gendron, & Barrett, 2017; Kragel & LaBar, 2016).

Most of us, at some point in our lifetimes, will feel all of the six basic emotions described by Paul Ekman: anger, sadness, happiness, surprise, fear, and disgust. What scientists now understand is that many of us also feel mixed emotions or nuances of these emotional states. Saarimäki and colleagues (2016), using fMRI imaging, scanned the brains of individuals while they watched movies that distinctly elicited one of the six basic emotions. What they found was that that the medial prefrontal cortex, medial parietal lobes, and select areas of the temporal and visual cortices were activated in all of the different emotional conditions. The amygdala, for example, often described as the brain centre for fear, was also active during movies portraying happiness and disgust. What this data and other imaging studies have shown is that there is no single structure of the brain linked to each of the six basic emotions. Rather, it is the activation of the circuitry between these

structures, in addition to the structures themselves, that is critical for our conscious experience of an emotion (Barrett, 2017; Saarimäki et al., 2016; Touroutoglou, Lindquist, Dickerson, & Barrett, 2015).

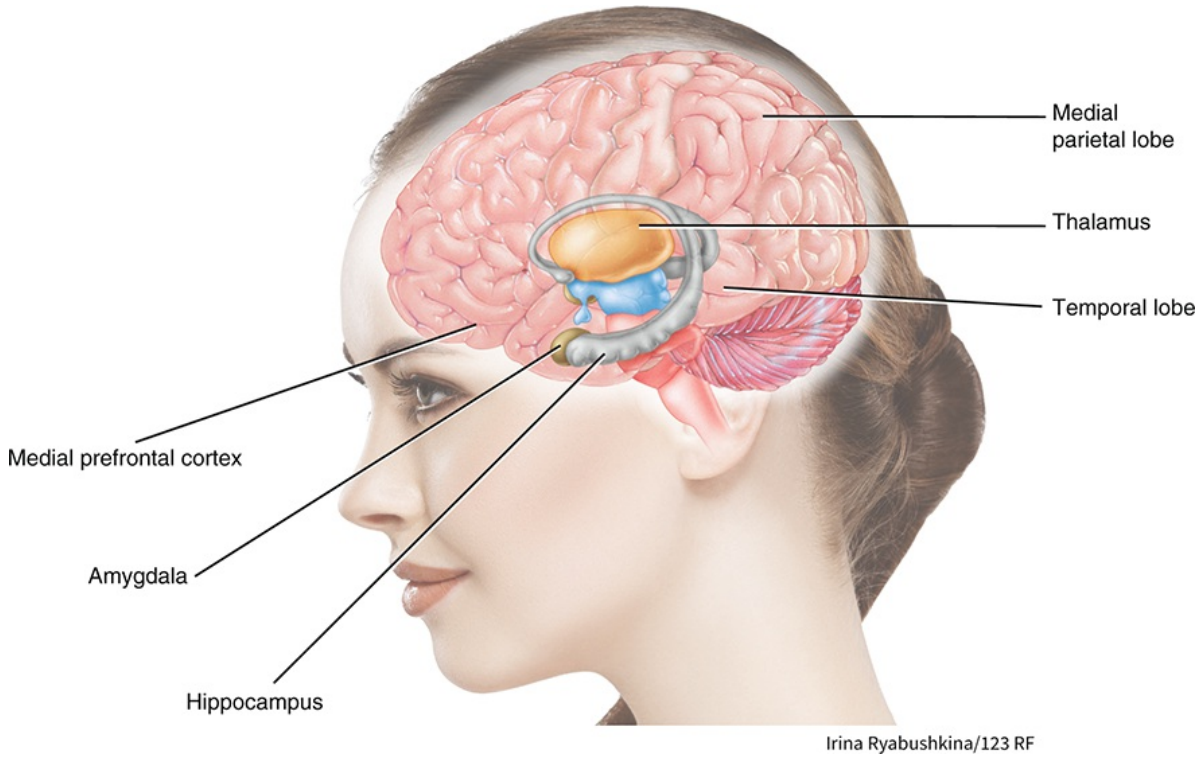

FIGURE 11.15 This figure shows a section of a human brain The medial prefrontal cortex, the medial parietal lobe, temporal lobe, thalamus, hippocampus, and amygdala, and the circuitry between these structures, contribute to our experience of emotions (Saarimäki et al., 2016).

What Do You Know?

24. What is the key idea in the James-Lange theory of emotion?

25. What are Cannon's arguments disputing this idea?

26. What element did Schachter and Singer's two-factor theory add to explanations of what determines emotional experience?

27. What is facial efference?

28. What does it mean to say that emotions have been shaped by natural selection?

What Do You Think? • Recall a powerful emotional experience you have had. Which of the theories of emotion detailed in this chapter seems to best explain your experience? Is one theory sufficient?

What About Positive Emotions?

LEARNING OBJECTIVE 8

Identify some factors that influence whether or not a person is happy.

After reading about the work of early emotion researchers, you may think that psychologists have a great deal to say about unpleasant or negative emotions, such as fear, anxiety, anger, and sadness, but less to say about how people experience pleasant, positive emotions, including happiness, pride, and excitement. The past decade, however, has witnessed a striking rise in research on positive emotions, particularly happiness. As you will recall from Chapter 1, a major new trend in the field of psychology is to focus on positive psychology (Seligman & Csikszentmihalyi, 2014; Seligman, 2007; Seligman & Steen, 2005). *Positive psychology* is the study and enhancement of positive feelings, including happiness and optimism; positive traits, such as perseverance and wisdom; positive abilities, such as interpersonal skills; and virtues that enhance the well-being of society, including altruism and tolerance (see photo). Consistent with this important new field of psychology, researchers are now conducting numerous studies on happiness. We have learned that it is indeed one of the most important and adaptive of human emotions.

XiXinXing/Getty Images

Positive psychology **According to positive psychology, positive life experiences play a role in the development of a large range of adaptive qualities such as optimism, perseverance, and wisdom.**

In fact, regarding happiness, the news seems to be quite good. Research indicates that people's lives are, in general, more upbeat than psychologists used to think. In fact, most

people around the world say they are happy—including most of those who are poor, unemployed, elderly, and disabled (Table 11.4) (Graham, 2012; Morgan, Robinson, & Thompson, 2015). Of course, happiness involves different things for different people.

Consider the following results:

Wealthy people appear only slightly happier than those of modest means (Bozionelos & Nikolaou, 2010; Graham, 2012; Jebb, Tay, Diener, & Oishi, 2018).

Although early studies suggested only a minimal relationship between age and happiness (Myers & Diener, 1997; Inglehart, 1990), more recent studies have found that, provided they remain healthy, people over 65 actually report more happiness and less negative emotion than do younger people (Morgan et al., 2015). (See photo.)

Over 90 percent of people with quadriplegia say they are glad to be alive, and overall, people with spinal cord injuries report feeling only slightly less happy than other people (Duggan et al., 2016).

No age limit People who are happy when younger tend to remain happy as they age. On average, older people are as likely as younger people to be happy, and perhaps more likely.

Men and women are equally likely to declare themselves satisfied or very happy. A longitudinal study published in the journal *Science* found that highly optimistic people had

a 55 percent reduced risk of death from any cause and a 23 percent reduced risk of heart problems, compared with highly pessimistic people (Giltay et al., 2004).

Some studies suggest that one's sense of happiness may have a genetic component (Bartels, 2015; Nes & Røysamb, 2017). Indeed, one of the most dominant factors in determining happiness may be temperament. Twin studies have found that identical twins' ratings of happiness are generally similar (Røysamb, Nes, Czajkowski, & Vassend, 2018), and in classic work by Veenhoven, (1984) it has been reported that the single best predictor of future happiness is past happiness. These findings may suggest that a temperamental predisposition to look at life optimistically is more important than an individual's life situation.

Research also indicates that happiness is linked to our personality characteristics and our typical ways of cognitively interpreting events (Csikszentmihalyi & Wong, 2014; Farah et al., 2014; Diener, Ng, Harter, & Arora, 2010). Recent work from Australia has shown that happy people are, for example, generally optimistic, outgoing, curious, and tender-minded (Soto, 2015). They also tend to possess high self-esteem, be spiritual, be goal directed, and have a sense of perseverance and of control over their lives (Diener, Seligman, Choi, & Oishi, 2018). (See Positive Psychology 11.2.)

11.2 Psychology Around Us | Positive Psychology

Happiness, Motivation, and Psychological Capital

Many college and university students feel stress. Feeling stressed can influence how well we manage the challenges of completing courses and juggling schedules between school and life demands. Having an orientation to happiness is a significant factor in being able to finish post-secondary education. How happy you feel can influence how much you engage in your studies and how motivated you feel to do well in your classes (Durón-Ramos, & García-Vázquez, 2018). Interdependent happiness can also influence how well people feel about themselves and how they do in school. The development of friend groups with other students who can work together to support each other's well-being and happiness can also motivate people to higher academic achievement. The study of interdependent happiness is a new area of psychological research that will be interesting to follow as we learn more about how we all can influence and support the happiness of others (Hitokoto & Uchida, 2015).

Happiness is also a key component of optimism, which fits under the umbrella of a concept often used in the workforce called psychological capital. Four different personal resources fit within the scope of psychological capital: self-efficacy, hope, resilience, and optimism. Having high psychological capital is correlated to higher levels of motivation and academic achievement (Datu, King, & Valdez, 2017, 2018). Increasing your happiness may increase your psychological capital and in turn increase your satisfaction and achievement with your post-secondary experience and ultimately your job. Happiness is a win-win strategy!

Pexels/9148 images/Pixabay

Jumping for joy **Happiness is a key component of optimism and your overall satisfaction with your education, future job, and life in general.**

It appears that good relationships are related to happiness and satisfaction. Married people tend to be happier than single people (although this effect may be stronger for men than for women) (Latif, 2016). Other social predictors of happiness include a society that individuals assess as being prosperous, with adequate food and health care (it isn't always about money), and strong social support networks (Diener & Seligman, 2018; Diener et al., 2018). Some countries, like Bhutan, not only measure their country's wealth, or gross domestic product, as an indicator of a healthy society, they also measure their country's "gross national happiness," which they see as more important than money (Thinley & Hartz-Karp, 2019). And in what may or may not be surprising news to you, college and university students who have close friends and significant others are happier than those who do not (Diener et al., 2018).

What Do You Think? • How would you advise a friend who asked you for tips on how he or she could be happier?

Summary

Theories of Motivation

LEARNING OBJECTIVE 1 Briefly explain each of the five major theories of motivation.

Several theories offer explanations for our motivation, but no single theory can explain all our behaviour.

Instinct theory, which suggests that environmental cues stimulate inborn behavioural instincts, best explains motivation that serves basic biological drives, such as eating, drinking, and sex.

Drive-reduction theory suggests that internal homeostatic mechanisms produce balance within the body by reducing arousal stemming from unmet basic biological needs.

Arousal theory explains why we sometimes seek to increase arousal levels. The Yerkes-Dodson law proposes that task performance is best if our arousal level matches that needed for a task.

Incentive learning produces extrinsic motivation to engage in experiences that do not fulfill basic biological drives. Primary and secondary incentives may both be involved. Different incentives motivate different people. Incentive motivation involves brain systems associated with pleasure, incentive learning, and the neurochemical opiate dopamine.

Maslow proposed that we are motivated by a hierarchy of needs, in which basic survival needs must be satisfied before higher-level needs for belonging, achievement, and self-actualization.

Biological Motivations: Thirst and Hunger

LEARNING OBJECTIVE 2 Summarize the factors that affect our motivation to drink and to eat.

Thirst is the biological drive to consume fluids. We need fluid inside and outside of our cells to maintain proper cellular functioning. Our bodies our approximately 60 percent water. While it is rare, some individuals can die from water intoxication.

Hunger, our motivation to eat, is created by the interaction of signals from our stomachs, levels of food-related chemicals in our blood, and brain activity, particularly in the hypothalamus.

Culture and individual differences interact with our basic biological need for food to determine what foods we will eat, when and with whom we like to eat, and how much we eat.

Obesity is a major public-health problem in North America. It is usually caused by overeating, which can result from an interaction between genes and the environment.

Anorexia nervosa is an eating disorder in which individuals believe they are fat and eat too little. Bulimia nervosa is an eating disorder in which people binge on food, then purge themselves of the food before it can add weight to their bodies. Binge eating disorder occurs when people gorge themselves on food over repeated sessions.

Biological Motivations: Mate Choice and Sex

LEARNING OBJECTIVE 3 Describe factors that affect our motivation to choose a mate and to have sex.

Several factors influence the people we choose to mate with, including age, body morphology, intelligence, and creativity.

Sexual practices driven by sexual motivation vary widely as a result of cultural influences.

Research consistently shows a great deal of variety in normal sexual behaviour throughout healthy adulthood.

Testosterone and other hormones affect our motivation for sexual behaviour. Many parts of our brains become active during sexual arousal and behaviour.

Psychological Motivations: Individual Factors

LEARNING OBJECTIVE 4 Describe how unconscious/conscious, approach/avoidance, intrinsic/extrinsic, and fixed/growth mindsets affect our motivational drive.

We are all driven by conscious and unconscious processes that influence our motivations to act.

All of us are influenced by internal motivation—doing something because it feels good—and external motivation—gaining a reward for a behaviour. In some cases, individuals are amotivated and do not have a drive to perform even the simplest of behaviours such as getting out of bed.

Approach motivation is the desire to work toward a goal that gives us pleasure versus avoidance motivation where we perform a behaviour to avoid a painful experience.

Growth and fixed mindsets can influence our motivational states.

Psychological Motivations: Affiliation and Achievement

LEARNING OBJECTIVE 5 Describe factors that influence our psychological motivations for affiliation and achievement.

Affiliation represents our need to interact with others, not only for survival, but also for self-worth.

Isolation puts people at risk of psychological impairments.

Self-determination theory suggests that we need competence, relatedness, and autonomy to realize our potential.

Achievement through intrinsic motivation does not involve incentives.

Individuals who are able to delay gratification can focus on goals and ignore distractions.

What Are Emotions?

LEARNING OBJECTIVE 6 Define emotion, types of emotion, and the components,

measurement, and functions of these emotions.

An emotion is an intrapersonal state that occurs in response to an external or internal event and includes three components: a physiological component, a cognitive component, and a behavioural component.

Researchers typically use three kinds of information to measure emotion: behavioural displays of emotion, self-reports of emotion, and physiological reactions.

Emotions serve many functions. They add colour to our lives, give us information about important events in the environment, stir us to action when necessary, and help us to coordinate relationships with others.

Theories of Emotion

LEARNING OBJECTIVE 7 Discuss the major theories of emotion, and identify the pathways through which emotions are experienced according to each theory.

The conventional common-sense explanation of emotion holds that an event triggers an emotion, which leads to physiological changes, followed by a response to the situation.

In contrast, the James-Lange theory proposes that the emotion we feel results from bodily and behavioural responses to environmental stimuli, rather than causing those responses.

According to the Cannon-Bard theory, physiological arousal by itself cannot produce complex emotional experiences. Rather, the perception of an emotionally stirring event simultaneously sends messages to parts of the brain responsible for the subjective experience of emotion and physiological arousal.

Schachter and Singer's two-factor theory holds that an emotional state is a function of both physiological arousal and cognition.

Building on Schachter and Singer's two-factor theory, cognitive-mediational theory proposes that cognitive interpretations, and particularly appraisals, of events are in fact the keys to the experience of emotions.

The facial-feedback theory of emotion, based on the ideas of Darwin, holds that facial expressions that occur in response to stimuli provide feedback to the brain that helps to shape emotional experience.

Evolutionary theorists believe that emotions have been shaped by natural selection and that certain emotions have been passed down because of their role in the survival of our species.

What About Positive Emotions?

LEARNING OBJECTIVE 8 Identify some factors that influence whether or not a person is happy.

Researchers have tended to focus on negative emotions, in part because of difficulties in measuring positive emotions.

Identifying what makes people happy can be difficult. Research has shown that good relationships, employment, and good health are among the things that can make people happy. In particular, though, temperament and personality predict happiness.

Self-Study Questions

Multiple Choice

1. Which theory of motivation best explains the non–goal-directed behaviours associated with curiosity?

a. Arousal

b. Drive reduction

c. Incentive

d. Instinct

2. The midbrain structure that contains dopamine neurons essential for reinforcement learning, and motivation, is the

a. corpus callosum.

b. hippocampus.

c. nucleus accumbens.

d. ventral tegmental area.

3. What brain structure sends "hunger" signals that cause an animal to eat?

a. Lateral hypothalamus

b. Pons

c. Thalamus

d. Ventromedial hypothalamus

4. Which theory of hunger motivation proposes that activity in the lateral hypothalamus serves to inhibit the ventromedial hypothalamus, and vice versa?

a. Arousal

b. Dual-centre

c. Incentive

d. Instinct

5. Blood levels of what hormone are positively related to sex drive in men?

a. Estrogen

b. Insulin

c. Progesterone

d. Testosterone

6. The psychological characteristic most strongly related to the ability to delay gratification is

a. impulse control.

b. need for achievement.

c. need for affiliation.

d. predestination.

7. The sweaty palms and rapid heartbeat we experience as anxiety are most directly related to activation of which portion of the nervous system?

a. Autonomic nervous system

b. Hippocampus

c. Occipital lobes

d. sympathetic nervous system

8. Which theorist suggested that physiological responses to a stimulus provide the basis for experiencing an emotion?

a. Cannon

b. James

c. Schachter

d. Watson

9. According to the Cannon-Bard theory of emotion, which structure relays information about an emotionally stirring event to the sympathetic nervous system?

a. Anterior cingulate cortex

b. Cerebellum

c. Frontal cortex

d. Thalamus

10. Which statement best describes the difference between the psychological needs for affiliation and for achievement?

a. Achievement is defined in the same way across different societies, but affiliation is

not.

b. Affiliation is a basic psychological need, but achievement is not.

c. Affiliation is less important than achievement.

d. Brain size influences the need for affiliation, but not achievement.

Fill-in-the-Blank

1. Research on arousal and task performance has shown that difficult tasks are best performed under conditions of _____ arousal.

2. The _____ theory of motivation looks to internal and external rewards as motivators of behaviour.

3. Rewarding stimuli often increases levels of the neurotransmitter _____ in the brain.

4. One biological factor related to obesity may be an insensitivity to _____, a protein used by the brain to regulate eating.

5. Masters and Johnson found that men, but not women, have a _____ period after orgasm during which time they cannot have another orgasm.

6. Social exclusion leads to measurable changes in the brain, particularly in the _____ region.

7. Research has shown that _____ motivation is related to beneficial psychological characteristics such as competence and autonomy.

8. A driver who swerves to avoid a crash, then notices that his breathing and heartbeat are rapid, is experiencing the _____ component of emotion.

9. The finding that most people with spinal cord injuries can still experience emotional arousal is supportive of the _____ theory of emotion.

10. Facial _____ refers to the idea that smiling can lead to a happier mood.

CHAPTER 12
Personality

Wavebreak Media ltd/Alamy Stock Photo

CHAPTER OUTLINE

The Psychodynamic Perspective

LEARNING OBJECTIVE 1 Summarize the main ideas of the psychodynamic view of personality development.

The Humanistic Perspective

LEARNING OBJECTIVE 2 Describe the humanistic theories of Abraham Maslow and Carl Rogers.

The Trait Perspective

LEARNING OBJECTIVE 3 Summarize the leading trait theories, and describe how the five-factor theory has evolved from the work of Gordon Allport and Hans Eysenck.

Personality Assessment

LEARNING OBJECTIVE 4 Describe the two major types of personality tests, and give examples of each.

The Situationist and Interactionist Perspectives

LEARNING OBJECTIVE 5 Describe and differentiate the situationist and interactionist views of personality.

Biological Foundations of Personality

LEARNING OBJECTIVE 6 Discuss the heritability of personality traits and some of the neural systems that may be involved in the expression of personality.

Differences in Personality

LEARNING OBJECTIVE 7 Explain how gender and cultural differences can affect personality.

Personality Disorders

LEARNING OBJECTIVE 8 Define personality disorders, and describe some of the key features of these disorders.

Michele Renard is a city girl, raised in the Jewish faith in Montreal. Cécile Corriveau was raised in the Catholic faith in the suburbs. Talking to them as they sit side-by-side in a room on campus, you can tell they grew up in different communities. Dark-haired Michele is dressed in the somber shades of urban chic, while Cécile sports sculpted hair, straightened teeth, and a white fur-lined jacket. Cécile has a car, while Michele does not.

The two students are at neighbouring universities in Montreal, Quebec. They share a birthday, they are exactly the same height, and they both love hip-hop.

The most important thing they share is the same parents. Separated shortly after birth and given up for adoption, for most of their lives they had no idea that somewhere out there was an identical twin.

But they have many similarities in spite of growing up in different homes. They are both night people, they both love to dance, they both want to have a boy and a girl (in that order), and they both use Pantene® shampoo. They are both "B" students, even though Michele attended a top private school and Cécile went to public school. And the subject that gives them both the most trouble? Math. They look remarkably alike, but they are not exactly alike. Michele has a birthmark over her right eyebrow, and Cécile had to wear braces for five years. Plus, Michele says she's a little more outgoing than Cécile, who admits she's a very shy person.

What makes us who we are? How do we explain the striking similarities between Michele and Cécile? Are they an interesting coincidence, or do they reveal something fundamental about the nature of personality?

Personality refers to the ways in which people differ in how they interact with one another socially and in how stable or unstable those characteristics are over time and situations. Personality, along with intelligence, is part of what is called *individual difference psychology*. Efforts to characterize the links between inner experience and outward behaviour go back centuries. Hippocrates (yes, the Hippocratic Oath) identified four distinct personality types: sanguine (into good times), phlegmatic (calm and wise), melancholic (withdrawn and darkly moody), and choleric (quick to anger and fight). The fact that you can probably name people you know that would fit into each of these types suggests that Hippocrates' observations usefully speak to one of two fundamental personality questions: What are the ways, or the dimensions along which, people differ or vary? As we will discuss later in this chapter, you have an implicit personality theory that you use every day to answer this question as you try to understand and predict the social behaviour of people around you and to understand your own behaviour. Like Hippocrates' work, your implicit personality theory is based on your observations and experience and you use it to decide what to expect from the people you know and you use it to make

lightning-fast decisions or first impressions about new people you encounter that determine whether or not you want anything more to do with them. The trait approach and the personality inventories it led to was initially grounded in addressing this first, "what," question.

> **personality** the unique characteristics that account for enduring patterns of inner experience and outward behaviour.

There is, however, a much bigger second personality question that has occupied much theoretic work and research in psychology because it is concerned with the question of "why" or "how" is it that people turn out the way they do? Many theories in psychology have tried to dig in to aspects of the "why" question, including how much of personality might be tied to biological predispositions, temperaments, or instincts, and how much might be explained by life experiences, parenting, education, and other social experiences and how stable or flexible is personality. As we discussed back in Chapter 4, psychologists and biologists have come to acknowledge that environmental experience and biological mechanisms work together to shape personality. In this chapter, we will first explore key historic perspectives on the "why" question in personality: the *psychodynamic, humanistic, trait, situationist*, and *interactionist* perspectives. We then look at the important role played by genetic predispositions in personality and what researchers have discovered about the contributions of both genetic and environmental factors. Next, we examine how personality is assessed in individuals and whether personality differs depending on gender and culture. And finally, we describe various personality disorders.

The Psychodynamic Perspective

LEARNING OBJECTIVE 1

Summarize the main ideas of the psychodynamic view of personality development.

As you read in Chapters 1 and 6, the psychodynamic (or psychoanalytic) model emphasizes the unconscious, often dark desires that have to be held in check. Recall also from those chapters that the model was formulated by the Viennese neurologist Sigmund Freud (1856–1939) at the beginning of the twentieth century. Freud, like his contemporary Charles Darwin (Moncayo, 2018), believed that a full account of human psychology and personality needed to include acknowledgement that humans, like other animals, have some basic wired-in drives of instincts. In Freud's broadly cast efforts to address the "why" question, the personality forms as a result of struggles between primal needs and social or moral restraints. Many other theorists who follow Freud's key principles differ from him in certain ways. However, they share his basic notion that personality and behaviour are shaped by interacting, or *dynamic*, underlying forces. Thus, all such theories, including Freud's, are referred to as *psychodynamic*.

FIGURE 12.1 Freud's view of the mind **According to Freud, the mind has three levels of consciousness. The content stored in the unconscious level is especially important for personality development.**

The Structure of Personality

Central to Freud's ideas are his views of the conscious and unconscious mind. To Freud, the mind is a little like an iceberg. Only the top of the massive entity is visible to the outside world (see **Figure 12.1**). Three levels of consciousness contain the information stored in our minds, but most of that information is not available to normal awareness.

The topmost level is the *conscious* mind, composed of the thoughts and feelings that we are aware of at any given moment.

The second level, just below the surface, is the *preconscious*, which contains thoughts, memories, and ideas that can be easily brought into the conscious mind if attended to. For example, your mother's birthday or your plans for this evening remain in your preconscious until you require the information, at which point the information is transferred into your conscious awareness.

The deepest level, the *unconscious*, contains most of the content of our minds. We are unaware of this content and cannot become aware of it except under special circumstances. The unconscious is particularly important to the development of personality.

Freud identified three central forces in personality development: basic instinctual drives (which he called the *id*), rational thoughts (the *ego*), and moral limits (the *superego*).

The **id** is present at birth and represents basic instinctual needs and desires, such as those related to eating, sleeping, sex, and comfort. These impulses are governed by the *pleasure principle*; that is, they constantly strive for gratification. Freud believed that most of these basic impulses have sexual overtones and that sexual energy, which he called *libido*, fuels

the id. Due to the simple nature of the id's needs and its urgent demand for satisfaction, the id is often described as immature and childlike or essentially mindless. The id resides largely in the unconscious and is not readily available to consciousness.

> **id** according to psychoanalytic theory, the personality element representing basic instinctual drives, such as those related to eating, sleeping, sex, and comfort.

As children grow older, they begin to learn that their id impulses are often not socially appropriate and thus cannot always be satisfied. The **ego** develops as a result of this learning. The ego works under the *reality principle*—the awareness that it is not always possible or acceptable to have all wants and desires met. Much like the id, the ego is responsible for satisfying impulses, but instead of demanding immediate and direct gratification, the ego first assesses what is realistically possible and what the social consequences of gratification might be. Freud essentially saw the ego as the rational, problem-solving force that constantly strives to keep id-based impulses from bursting forth in a destructive manner. From this description, you might conclude that the ego is largely a product of the conscious mind, but Freud believed that it works both consciously and unconsciously.

> **ego** according to psychoanalytic theory, the personality element that works to help satisfy the drives of the id while complying with the constraints placed on behaviour by the environment.

The **superego** also forms during childhood. It is in charge of determining which impulses are acceptable to express openly and which are unacceptable. The superego develops as children observe the behaviours of those around them in their families and their culture. As children, we *internalize*—or unconsciously adopt—the values and norms embodied in those behaviours and begin to evaluate ourselves with respect to them. The superego's standards of right and wrong comprise our moral code and remain stable over the course of our lives. Our superego might therefore be thought of as our *conscience*—an entity that leads us to feel guilt and sometimes even anxiety. Like the ego, the superego resides in both the conscious and the unconscious mind.

> **superego** according to psychoanalytic theory, the personality element in charge of determining which impulses are acceptable to express openly and which are unacceptable; develops as we observe and internalize the behaviours of others in our culture.

According to Freud, the ego acts as a mediator between the id and superego. That is, it balances the powerful desires of the id with the moral standards of the superego. Freud believed that the three forces are always in conflict to some degree. Usually, the conflict takes place at an unconscious level. What if these conflicts are not resolved? Personality problems and even psychological disorders may result if a person is not able to find acceptable compromises.

Freud's Psychosexual Stages

Freud believed that as the id, the ego, and the superego work with and against one another, children move through stages that result in the development of personality. The two drives that influence these stages most strongly are *sexuality* and *aggression*. To Freud, these drives are the most likely to cause internal conflict because they are the ones that most often fall under social and moral constraints and are most likely to be left unsatisfied. Accordingly, the stages of development are termed **psychosexual stages**. Several are named after specific *erogenous zones*, or pleasure-producing areas of the body. As shown in **Table 12.1**, Freud labelled the stages *oral*, *anal*, *phallic*, *latency*, and *genital*.

> **psychosexual stages** according to psychoanalytic theory, stages in the development of personality; the stages—labelled oral, anal, phallic, latency, and genital—are primarily influenced by sexuality and aggression.

Muralinath/iStockphoto

Oral personality in the making? Freud proposed that individuals whose nurturance needs are not adequately met during infancy may become fixated and develop an oral personality style. They may, for example, be inclined to suck their thumbs even during later childhood, chew their nails, smoke cigarettes, and show signs of dependence.

Freud believed that the psychosexual stages function as learning periods that can produce many individual differences in personality. Children must successfully complete, or *resolve*, the issues of each stage to form a healthy personality. As children move into a new stage, they must cope with new demands from the social environment and conflicting internal feelings. If they do not successfully resolve the conflicts that arise, they may become *fixated*, or mentally stuck at that stage of development. Freud hypothesized that a fixation may affect all subsequent development.

Freud linked fixation at different psychosexual stages to the development of distinct, sometimes abnormal, personality characteristics (see photo). For instance, Freud believed that a boy in the phallic stage focuses on his penis and a girl on her lack of a penis (so-called *penis envy*). A boy entering the phallic stage also begins to feel sexual attraction toward his mother and jealous rage toward her love interest, his father. Freud called these feelings the

Oedipus complex, after the character in Greek mythology who inadvertently killed his father and married his mother. At the same time, the boy fears that his father will punish him for his feelings, perhaps by cutting off his source of sexual function, his penis (so-called *castration anxiety*). These feelings, of course, are unconscious, and the child's attempts to resolve the conflicts they create also occur largely at the unconscious level. If children fail to resolve such conflicts, they may suffer from **neuroses**, Freud's term for abnormal behaviour patterns characterized by anxiety, depression, and other such symptoms.

neurosis an abnormal behaviour pattern caused by unresolved conflicts between the id, ego, and superego.

Anxiety and Defence Mechanisms

We have seen that internal psychological conflict, often resulting in anxiety, is central to personality development in psychoanalytic theory. Because humans cannot constantly live in an unsettled state of anxiety, they must have some effective methods for handling it—methods for keeping the id forces in check. This realization forms the basis for one of Freud's major contributions to how human beings think about themselves: **defence mechanisms**. Freud described defence mechanisms as unconscious tactics employed by our egos to protect us from anxiety by dealing with id impulses. **Table 12.2** lists and describes some defence mechanisms.

defence mechanisms unconscious tactics employed by the ego to protect the individual from anxiety.

TABLE 12.1

Freud's Psychosexual Stages

Stage	Erogenous Zone	Key Conflict or Experience	Symptoms of Fixation
Oral (0–18 months)	Mouth	Weaning	Dependency on pleasures of the mouth; also general dependence on mother
Anal (18 months–3 years)	Anus	Toilet training	Excessive neatness, orderliness, stubbornness, stingy, controlling
Phallic (3–6 years)	Genitals	Attraction to opposite-sex parent	Sexual role rigidity or confusion
Latency (6 years–puberty)	None	Repression of sexual impulses; identification with same-sex parent	No fixations for this stage
Genital (puberty–	Genitals	Establishing mature sexual relations and emotional	Sexual dysfunction and unsatisfactory relationships

adult)		intimacy	

Repression is the most basic defence mechanism. This strategy keeps unpleasant memories or thoughts buried deep within our unconscious minds, protecting us from the difficult and painful process of facing them. Another frequently used defence mechanism, and one that has entered into our common vocabulary, is **denial**. This occurs when a person simply refuses to recognize an existing situation. A person who gambles constantly, for example, may claim that she doesn't really gamble that much or that, even if she does, it isn't a problem and she can quit anytime. Denial can also be seen in historic mainstream beliefs regarding retirement of Canada's First Nations People (see Indigenous Experiences 12.1). It's important to remember that, as stated above, defence mechanisms are unconscious tactics. Thus, the gambler in our example is not consciously making excuses for her behaviour when she practises denial. Examples of other defence mechanisms are described in **Table 12.2**.

repression the most basic defence mechanism; the process of keeping unpleasant memories or thoughts buried deep within the unconscious mind.

denial a defence mechanism; the process of refusing to recognize an existing situation.

12.1 Indigenous Experiences

Denying Our Past

Denial is an unconscious defence mechanism used to protect us from uncomfortable truths. Denial has played a significant role in the justification, obfuscation, and rejection of the facts in relation to Canada's colonial history.

Many Canadians see themselves as living in a country of overly apologetic people who are polite, decent people who care about others and have a strong moral centre. But Canada's colonial history stands in sharp contrast to that perception (Stromquist & Knickerbocker, 2015). To this day, denial about the treatment of Indigenous people has taken many forms, such as the following:

> On the heels of his apology to Indigenous leaders and survivors on the floor of the House of Commons in 2008, then-Prime Minister Stephen Harper told those attending the G20 Summit in 2009: "We also have no history of colonialism" (Strakosch, 2015, p. 20).
>
> **Facts:** The Indian Act, residential schools, forced relocation of Indigenous peoples, imposed band council system, outlawing of cultural ceremonies and traditions, and so on. (Strakosch, 2015; Truth and Reconciliation Commission, 2015).
>
> Indigenous children were provided with education and opportunities they would not have received without access to residential schools (Stromquist & Knickerbocker, 2015).
>
> **Facts:** Although some Indigenous survivors report positive experiences in

residential schools, the majority report receiving an inferior education, often educated to only Grade 5, experiences of abuse and neglect, overcrowding, stolen identities, forced manual labour, inadequate nutrition, and deliberate attempts to undermine their languages and cultures. Moreover, many children did not live to talk about their experiences. The National Residential School Student Death Register lists the names of 3200 children who died while in residential schools. However, this number is considered to be low, with closer to 6000 children presumed dead. Many parents never knew what happened to their children. The Missing Children Project is seeking to complete the national register to document the burial places for all of the Indigenous children who never returned home (Truth and Reconciliation Commission, 2015).

Government officials were not aware of the conditions in the residential schools (Stromquist & Knickerbocker, 2015).

Facts: The Canadian government played a central role in the creation and maintenance of the residential school system. The system was underfunded and mismanaged, with tragic consequences. In 1907, Dr. Peter Henderson Bryce, Canada's first Chief Medical Officer, and an expert on tuberculosis (TB), visited 35 residential schools and issued a report condemning the appalling health conditions he encountered there. He argued that TB and other illnesses were responsible for the deaths of 24 percent of children in the residential schools he visited. He recommended solutions and persistently wrote to officials responsible for the schools, demanding action. His position was then abolished. In 1922, upon retirement, he published his findings: *The Story of a National Crime being an Appeal to the Justice of the Indians of Canada* (Milloy, 2017).

THE CANADIAN PRESS/Justin Tang

National Residential School Memorial Register Joyce Hunter and Stephanie Scott, from the National Centre for Truth and Reconciliation, carry a ceremonial cloth depicting the names of 2,800 children who died while in residential schools. Joyce's brother, Charlie Hunter, is among those named. He died at St. Anne's Residential school in 1974.

Until the Truth and Reconciliation report in 2008 and the subsequent government apology, many Canadians did not even know about the existence of residential schools and what occurred there. For many, that is still true today. "This denial [makes] it easy to blame the victims for the inevitable consequences of cultural breakdown, family dysfunction, poverty, addiction, and incarceration" (Stromquist & Knickerbocker, 2015, p. 18).

Critical Thinking Questions

In what ways have Canadians been in denial regarding the experiences of Indigenous children in residential schools?

How is victim-blaming linked to both current general attitudes toward Indigenous people in Canada and non-Indigenous Canadians' limited awareness of the residential school experiences?

What steps might be taken to try and reduce the level and extent of denial within the general Canadian population regarding the residential school experiences of Indigenous Canadians.

TABLE 12.2

Some Common Defence Mechanisms

Mechanism	Description	Example
Repression	Keeping unpleasant memories or thoughts buried in the unconscious	Forgetting the details of a tragic accident
Denial	Refusing to recognize an unpleasant reality	Refusing to admit an addiction: "I don't have a problem" or "The emperor's new clothes are lovely!"
Rationalization	Creating a socially acceptable excuse to justify unacceptable behaviour	Justifying cheating on taxes because "everyone does it"
Reaction formation	Not acknowledging unacceptable impulses and over-emphasizing their opposite	Overpraising a sibling's accomplishment even though you resent his/her success
Projection	Transferring one's unacceptable qualities or impulses to others	Not trusting a co-worker but believing the co-worker does not trust you
Displacement	Diverting one's impulses to a more acceptable target	Yelling at family members after being yelled at by your boss
Sublimation	Channelling socially	Redirecting aggressive behaviour by

	unacceptable impulses into acceptable activities	becoming a professional fighter
Regression	Reverting to immature ways of responding	Throwing a tantrum when frustrated
Identification	Enhancing self-esteem by imagining or forming alliances with others	Joining groups for their prestige value
Intellectualization	Ignoring troubling emotional aspects by focusing on abstract ideas or thoughts	Discussing various economic theories while ignoring the pain of losing your job

A guilty conscience Preschool children start to show that they feel guilt when they cause damage or harm.

Evaluating Freud's Theories

The popularity of psychoanalytic theory was at its highest in the mid-twentieth century. Even today, many of Freud's ideas continue to influence the development of the field (Allen, 2015; Dumont, 2010; Colace, 2018; Levin, 2018). However, since the mid-twentieth century, when the popularity of psychoanalytic theory was at its highest, Freud's theories have come under significant criticism in the scientific community. Such criticism is largely due to the fact that the key principles of psychoanalytic theory are based on observations that cannot be directly tested by scientific methods (Zepf, 2018).

Freud based his theories on the cases of patients he treated in his private practice as a neurologist. When presented with puzzling symptoms, Freud pieced together clues from

the patient's childhood to try to identify the cause. For example, one of his patients—a 5-year-old boy called Little Hans—had developed an intense fear of horses (Freud, 1909, 1961). Freud came to believe that the boy's anxiety was a product of his psychosexual development related to his relationship with his father. In a lengthy summary of his treatment of Hans, Freud described his procedure for helping the father and son learn to address the repressed feelings that were leading to Hans's anxiety.

Freud's case studies, such as that of Little Hans, are effective at characterizing and classifying certain types of observed behaviours. Indeed, Freud's theories can provide an explanation for almost any type of observed behaviour (see photo). For example, we might say that a man who keeps getting into fist fights is redirecting angry, unresolved feelings of aggression toward his parents onto his various acquaintances in life. At the same time, we might say that another man, who is unhappy but not hostile, is repressing those same feelings of aggression. In both cases, we have explained the man's behaviour (or non-behaviour). But recall that psychologists seek to predict as well as to describe and explain. Based only on the knowledge that a particular man has unresolved feelings of aggression toward his parents, could we predict whether or not he will be prone to hostile and fighting relationships? Probably not. This lack of predictive power is a key weakness of psychoanalytic theory.

Fertnig/IStockphoto

Jose Luis Pelaez Inc/Blend Images/Getty Images

Setting the stage **Freud was among the first theorists to hold that parent–child relationships influence how people feel about themselves and how they handle intimacy as adults. It is obvious which of the interactions pictured here represents a healthier approach to correcting a child's mistakes, according to Freud.**

Additionally, many of Freud's observations were based on a very small and select population of upper-class individuals from nineteenth-century Vienna. This raises questions about the theory's cross-cultural validity and highlights the fact that Freud's ideas were based on his particular—and at times narrow—views of sexuality and parenting norms, and his especially narrow views of gender roles.

At the same time, Freud's supporters argue that it is unfair to criticize psychoanalytic theory for not holding up to scientific testing when it was never intended to act as a predictive model. Rather, Freud's fundamental claim was that individuals can find meaning from looking into their past (Rieff, 1979).

On the positive side, many general aspects of Freud's theory remain relevant today, such as the idea that our relationships with our parents can influence how we form intimate emotional relationships in adulthood (Briere et al., 2017; Blanchard, Lyons, & Nelson, 2014; Richter, 2013). (See photos.) In addition, some studies on defence mechanisms suggest that they are observable and can have important functions in both development and psychological disorders (Bhatia et al., 2016; Perry & Bond, 2012).

Perhaps most importantly, Freud's ideas spurred the first inquiries into the functioning of the conscious and unconscious aspects of the mind and how they relate to behaviour. The study of the unconscious mind has accelerated in the last two decades (Kihlstrom, 2019). As you learned in Chapters 6 and 8, numerous studies indicate that much of the information processed by the mind remains unconscious, and people rely on a variety of automatic processes to function in the world.

Other Psychodynamic Theories

Over time, some of Freud's followers, disagreeing with aspects of Freud's theory, split away to form their own schools of thought, becoming what are called *neo-Freudians*. Three of Freud's most notable followers were Alfred Adler, Carl G. Jung, and Karen Horney. The theories of the neo-Freudians departed from Freud's in important ways. But, as you read earlier, each held on to Freud's basic belief that human functioning is shaped by interacting, or *dynamic*, psychological forces.

Anna Peisl/Corbis/Getty Images

Moving beyond inferiority **Adler proposed that a child's inevitable experiences of helplessness produce early feelings of inferiority, which can lead to a lifelong sense of inferiority or to a lifelong quest for completeness and superiority.**

Alfred Adler

Alfred Adler (1870–1937) believed that social needs and conscious thoughts are more important to human behaviour than sexual needs and other unconscious motivations. Adler was particularly interested in how feelings of *inferiority* motivate behaviour. In Adler's view, almost everyone has some feelings of inferiority stemming from childhood experiences of helplessness (see photo). People often make special efforts to compensate

for or mask those painful feelings. Adler focused, in particular, on how feelings of inferiority are channelled into a quest for superiority. Although Adler's school of *individual psychology* has not had a major impact on personality theory, his ideas about how the need for power shapes human behaviour have gained momentum in contemporary research (Miller & Dillman Taylor, 2016; Maniacci, Carlson, & Sackett-Maniacci, 2017).

Carl Jung

Unlike Adler, Carl G. Jung (1875–1961) agreed with Freud's views on the importance of the unconscious. However, he added a new dimension: the collective unconscious. In Jung's system, the unconscious has two parts. The *personal unconscious*, formed from individual experiences, is similar to the unconscious as seen by Freud. The *collective unconscious*, however, is not a private entity like the personal unconscious. Instead, it is a cumulative storehouse of inherited memories shared by all humankind. Jung called these shared memories *archetypes*. According to Jung, archetypes are reflected in symbols and images that appear in the art, literature, and religions of all cultures. The archetype of the hero, for example, can be found in the stories of almost any cultural tradition, while an archetype of mother and stepmother can be seen throughout children's fairy tales (Garry, 2017).

Michael Macor/San Francisco Chronicle/Polaris Images

The positive drives of personality **Artist Frances Dunham Catlett (1908–2014) speaks about her work at a reception celebrating her "century of creativity." Carl Jung believed that unconscious drives toward joy and creativity are powerful forces in personality.**

Jung's *analytical psychology* also differed from psychoanalytic theory in the emphasis placed on sexuality and aggression. Jung acknowledged the importance of these forces, but argued that the unconscious also includes drives toward joy, creativity, and internal harmony (Wilde, 2011). (See photo.) Indeed, the search for harmony is a central theme of Jung's theory (Schmidt, 2019). He believed that each of us seeks to integrate the mind's various conscious and unconscious elements into a coherent whole, which he termed the *self* (see Practically Speaking 12.1).

Karen Horney

Another neo-Freudian, Karen Horney (pronounced HORN-eye) (1885–1952), accepted many of the basic principles of psychoanalysis, but went on to develop her own orientation and school of psychoanalytic training. Horney agreed with Freud that anxiety-provoking experiences in childhood can lead to lasting psychological problems, but she was particularly interested in what she called *basic anxiety*, which develops in children who experience extreme feelings of isolation and helplessness. Basic anxiety, in Horney's view, sets the stage for later neuroses.

Perhaps Horney's greatest disagreement with Freud related to the role of cultural influences on behaviour. To Freud, the basic conflicts that shape development are universal, but Horney observed distinct differences in personality structure between patients from Europe and those from the United States. She came to believe that cultural differences play a more important role in development than traditional psychoanalytic theory acknowledged. Horney rejected Freud's theories about penis envy, suggesting that what Freud was really detecting was women's envy of men's power—power that came from cultural norms, not inherent differences (Forsythe, 2019).

12.1 Practically Speaking

Jung in the Business World

In the 1940s, a mother–daughter team, Katharine Cook Briggs and Isabel Briggs Myers, created the Myers-Briggs Type Indicator (MBTI). Today it is one of the most well-known personality tests. Employers in various job fields, employment agencies, and job counsellors administer the questionnaire to several million individuals each year, though it is not appropriate for use in hiring decisions (Emre, 2018; Youngman, 2017; Wilde, 2011). The test is popular because it describes how we interact with our environment as well as with other people and can help us to see ways in which people can be different without being better or worse than others. This knowledge can be extremely useful for a manager in charge of a team of employees (and for the employees themselves) from diverse backgrounds, for example. As well, it can be very helpful for individuals in organizational settings to help them figure out why their interactions with their co-workers typically go the way they do.

The MBTI is based on Carl Jung's theory of personality types, and it describes personality in terms of individual preferences for perceiving and judging the world (Emre, 2018; Montequin et al., 2013). Do you prefer a more social or solitary environment? How do you interpret the information you take in? When you make a decision, do you first think about it logically or emotionally? Are you open to several possibilities? Your answers describe your basic preferences and, theoretically, reveal a lot about the kinds of jobs you would most enjoy (Wilde, 2011; Myers et al., 1998). Knowing your preferences may also provide clues about your strengths and weaknesses at work. One thing the MBTI cannot inform you or a prospective employer about is your abilities (McCrae & Costa, 1989); it cannot tell you how well you will perform a particular job and as such it should not be used in hiring decisions.

Most psychologists warn against basing career decisions only on the MBTI (Weber,

2015). Although the test may inform you that you meet the criteria of an introverted type, this does not mean that you should avoid that sales job you were coveting. Your categorization as an introvert does not mean that you are totally lacking in extroversion qualities, nor does it mean that you cannot behave in an extroverted manner when the social/work situation calls for it. Moreover, success at the job depends on many variables beyond extroversion or other such personality traits. And finally, for most jobs, a variety of different approaches can lead to success.

efenzi/Getty Images

Recall earlier discussions about the difference between correlation and causation. Remember that *correlation does not imply causation*; that is, simply because variables are correlated does not mean that one of the variables *causes* the other. So even though you may have a number of characteristics that indicate you might be an introvert, this does not mean that these characteristics will cause you to succeed in one line of work over another; these characteristics simply tell us that, in general, introverts excel in certain types of jobs.

Before You Go On

(Answers to Before You Go On may be found online in the Course Resources.)

What Do You Know?

1. In Freudian theory, how does a neurotic personality develop?

2. What is repression?

3. What are some common criticisms of psychoanalytic theory?

4. How did Jung's idea of the unconscious differ from Freud's?

What Do You Think? • Why do you think the concept of defence mechanisms has been embraced by so many theorists (even those who are not psychodynamic) and by the public?

The Humanistic Perspective

LEARNING OBJECTIVE 2

Describe the humanistic theories of Abraham Maslow and Carl Rogers.

Psychodynamic theorists, particularly Freud, generally believe that personality development is driven by deep instinctual forces that are largely beyond our control. Humanistic psychologists offer a different view. As you first saw in Chapter 1, they emphasize people's potential and highlight each person's consciousness, free will, and other special human qualities. Let's consider the ideas of two key humanistic theorists: Abraham Maslow (1908–1970) and Carl Rogers (1902–1987).

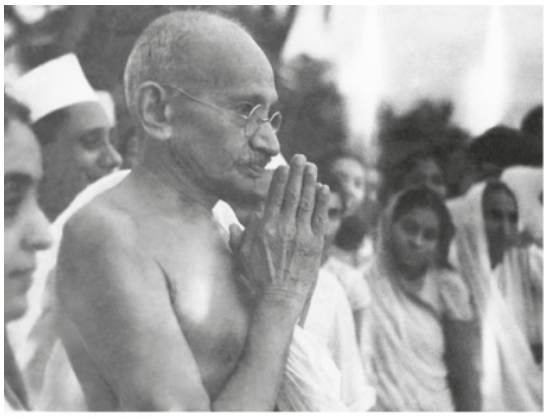
Abraham Maslow

Chapter 1 pointed out that Abraham Maslow believed humans are basically good. In each of us, according to Maslow, is an urge to grow and fulfill our potential. Personality arises from people's striving to meet their needs (D'Souza & Gurin, 2016). As you saw in Chapters 1 and 11, these needs are arranged hierarchically, beginning with the need for basic physiological necessities, such as food and shelter, and becoming increasingly complex. Only after our basic needs have been met can we address more subtle needs and strive to attain more complex things. Our highest-level need is **self-actualization**—the need to fulfill our full and special potential as human beings. Maslow described self-actualization as "the full use and exploitation of talents, capacities, [and] potentialities" (1970, p. 150). He suggested that psychologists had become overly focused on biological drives and needs, overlooking the role of high-level processes and the need for more complex forms of fulfillment.

> **self-actualization** the need of humans to fulfill their full and special potential; the highest level of need in Maslow's hierarchy of needs.

Unlike Freud, Maslow believed that more could be learned from individuals who were healthy and well-adjusted than from those who were experiencing psychological problems. In fact, he based his notion of self-actualized individuals on notable historical figures who appeared to lead rich and healthy lives: Albert Einstein and Eleanor Roosevelt, for example (Peterson, Park, & Seligman, 2013; Peterson & Park, 2010). The characteristics that define self-actualized people are the ability to recognize the needs and desires of others, the

willingness to respond to the uniqueness of people and situations rather than responding in mechanical or fixed ways, an emotionally deep connection with a few people, spontaneity and creativity, and the ability to resist the urge to conform while still responding to reality (see photos). In First Nations communities Elders are given significant respect and standing for the wisdom they have accumulated over their lives (see Indigenous Experiences 12.2).



Dinodia Photos/Getty Images

Alex Raths/iStockphoto

Candidates for self-actualization **Maslow proposed that self-actualized people also recognize the needs of others and seek to address them. He believed that full self-actualization was rare. However, well-known people like Bill Gates, Bono, and Gandhi are considered to be self-actualized because of their worldwide humanitarian undertakings. However, it is important to note that many people who recognize and seek the needs of others are not self-actualized; consider the case of the volunteer hospice worker who gives selflessly of her time and energy simply to help others.**

Some of Maslow's ideas have been taken up by psychologist (Mihaly Csikszentmihalyi 2020; Mao et al., 2016). Csikszentmihalyi studied *peak experiences*—moments in which people experience intense clarity of perception, feelings of joy and excitement, and a suspended sense of time and reality. Maslow thought that such moments usually occur when a person becomes totally engrossed in an activity, such as when we hear a beautiful piece of music or experience the beauty of nature. Csikszentmihalyi's writings on peak experiences reflect psychologists' growing interest in **positive psychology**, the study of positive experiences and healthy mental functioning involving things like simple acts of kindness (see Positive Psychology 12.1) and other things that we discussed in Chapter 11 (Lopez, Pedrotti, & Snyder, 2018; Seligman, 2019).

positive psychology an area of psychology focusing on positive experiences and healthy mental functioning.

12.2 Indigenous Experiences

Wise Elders as Knowledge Keepers and Transmitters

Elders have long been considered knowledge-keepers and transmitters of Indigenous spirituality, wisdom, and history, and in this role, they are vital to transmitting cultural and spiritual traditions and practices (Smylie et al., 2014). Elders play a key role because they are recognized as having earned the right to teach and to provide guidance and advice to individuals and to the larger community. Although the specifics of the role vary from one community to another, Elders all serve as role models for traditional practices and share a deep spirituality embodied in their lives and reflected through the harmony and balance of their actions (Rowe et al., 2020). Elders teach in their communities about history, language, and cultural knowledge as it has been historically handed down in spiritual ceremonies and oral traditions.

Being an elder is not defined by age or by gender. Elders are not all old and not all old people are Elders. Instead, Elders are chosen by their communities based on their life experiences, wisdom, and leadership. Many Elders have experienced adversity; some have experienced family separation, drug or alcohol addiction, survived residential schooling, and others have experienced different struggles. But an Elder has learned from the experiences of their life, turned to traditional culture for support and healing, and is committed to helping others. Elders believe in and teach respect for the natural world and the interconnectedness of all things (Smylie, Olding, & Ziegler, 2014). Survivor Isabelle Knockwood grew up in the Mi'kmaw community in Nova Scotia. She was taught to respect Elders. "They knew the seasonal cycles of edible and medicinal plants, and the migrations of animals, birds and fish, and they knew which hunting and trapping methods worked best with certain weather conditions" (Truth and Reconciliation Commission, 2012, p.8).

Since many Indigenous communities are currently experiencing an interruption in the intergenerational circle as young people increasingly reject their roots (Rowe et al., 2020), the "importance of preserving Elders' wisdom and sharing cultural knowledge and oral traditions across generations" is key (Freeman et al., 2020, p. 284). Residential schools damaged multiple generations, leaving each generation with unhealed trauma. "As a result, each generation of returning children had fewer and fewer resources upon which to draw" (Truth and Reconciliation Commission, 2012, p. 77). For example, Pierre Papatie said that in residential schools, he learned colonized versions of history and the textbooks contained "images that were telling us that, that the Elders were, savages who massacred missionaries. It was written in, it was in all, we were seeing that in the images in the history of Canada. That's what hurt me. That's what made me hate my father, even my father. Even all the Natives, I hated them all" (Papatie, 2012, p. 124–125).

Boomer Jerritt/All Canada Photos

Knowledge-keeper and transmitter Elder Evelyn Windsor poses for a portrait in Oweekeno, British Columbia.

To counter this intergenerational break, Anishinaabe scholar and activist Leanne Simpson worries that "reconciliation subjugates treaty and nation-based participation by locking our Elders—the ones [who] suffered the most directly at the hands of the residential school system—into a position of victimhood. Of course, they are anything but victims. They are our strongest visionaries, and they inspire us to vision alternative futures" (Simpson, 2011, p. 22.).

Critical Thinking Questions

"Elders are chosen by their communities based on their life experiences, wisdom, and leadership." How does this statement relate to the concept of self-actualization as presented in the chapter?

What important roles do Elders play in the culture of their communities?

Looking forward into the future, what steps should be taken or supported to ensure that cultural continuity provided within Indigenous communities by Elders continues?

12.1 Psychology Around Us | Positive Psychology

Random Acts of Kindness

It is likely that all of you have heard about the idea of random acts of kindness; maybe you've even done one of these for someone else. These acts can range from buying

someone's meal at a restaurant, offering your seat on a subway to someone who is elderly, saying a heartfelt thank you to someone who has gone out of their way to help you, or just picking up garbage in a local park. Learning to do random acts of kindness, and the co-development of compassion for others and our environment, may be of particular use to individuals who score low on agreeableness on the Big Five Personality Trait Inventory.

The personality dimension of low agreeableness is often associated with a tendency to engage in conflict, unfriendly behaviour, and at times overt hostility. In a recent study by Mongrain and colleagues (2018), they tested whether individuals with the personality trait of low agreeableness would benefit from completing acts of kindness toward others. This online study assigned participants who had scored low on agreeableness using the Big Five Personality Trait Inventory (John & Srivastava, 1999) to complete one of three tasks: a control condition where they were asked to journal daily about their interpersonal relationships, a compassion exercise that involved a loving-kindness meditation, and a condition where they had to perform acts of kindness. They did these activities every other day for three weeks. The researchers found that the loving-kindness meditation and acts of kindness reduced depression scores in both groups compared with the control group. What was even more interesting is that those individuals who were low in agreeableness and did the acts of kindness compassion intervention reported increases in life satisfaction, even two months after the study concluded (Mongrain, Barnes, Barnhart, & Zalan, 2018)! To add support to these findings, a recent meta-analysis showed that random acts of kindness could improve how we feel about ourselves (Curry et al., 2018). While this is only one study looking at the effects of acts of kindness on people with low agreeableness, it is an interesting finding that is worthy of follow-up study.

Ariel Skelley/Blend Images/Getty Images

Simple acts of kindness **A simple gesture of giving can provide positive benefits to both the recipient and the giver.**

Carl Rogers

Carl Rogers, like Maslow, believed that human nature is fundamentally positive and that people strive for self-actualization (Rogers, 2008, 1963). However, Rogers based his theory of personality around the concept of the *self* rather than around a hierarchy of needs. For Rogers, **self-concept** is a pattern of perception that remains consistent over time and can be used to characterize an individual. Our self-concept is related both to how we see ourselves and to how others see us. Because self-concept develops in part based on how we are perceived by others, as children we need **unconditional positive regard**—acceptance without terms or conditions—from parents or other adults to develop healthy self-concepts.

self-concept a pattern of self-perception that remains consistent over time and can be used to characterize an individual.

unconditional positive regard acceptance without terms or conditions.

The idea of unconditional positive regard became a central part of Rogers's therapeutic practice. He believed that, over the course of development, many children form *conditions of worth*, a perception that they must meet certain standards to gain the love of their parents or other important figures. These conditions of worth, often rigid or harsh in nature, can hold over into adulthood and act as a negative force that prevents a person from reaching his full potential. The implications for therapy are clear. In Rogers's *client-centred therapy*, discussed in Chapter 1, he worked with clients to create an atmosphere of openness, honesty, and absence of judgment, regardless of the specific type of psychological problems the persons were experiencing. He believed that only in such an atmosphere can individuals begin to put aside the conditions of worth that lie at the root of their personal maladaptive functioning (Zuroff et al., 2016; Rogers, 1995).

Evaluating Humanistic Theories

Many critics fault the humanistic theories for their overly positive focus, saying that they are simplistic and that they ignore the role of psychological dysfunction in society. In addition, it has been difficult for researchers to conduct controlled studies on such abstract concepts as self-actualization and unconditional positive regard (Krems, Kenrick, & Neel, 2017; Farber, Suzuki, & Lynch, 2018). However, humanistic theories have had a pervasive influence on the field of psychology. As mentioned above, and elsewhere in the textbook, researchers in positive psychology are giving new attention to questions about how human beings can achieve their full potential for happiness. It remains to be seen how humanistic psychology will contribute to this ongoing discussion.

6. According to Rogers, what happens if children fail to regularly receive unconditional

positive regard?

7. What is a key criticism of humanistic theory?

What Do You Think? • What do you think are the key qualities of a fully self-actualized person? Who might match your characterization?

The Trait Perspective

LEARNING OBJECTIVE 3

Summarize the leading trait theories, and describe how the five-factor theory has evolved from the work of Gordon Allport and Hans Eysenck.

The units or building blocks that personality psychologists use to describe personalities are called traits. On one level, traits are simply terms (adjectives) used to describe people. Table 12.3 contains some examples of personality trait terms. From the list, see if you can find *one* word that *best* describes who you are, over a wide variety of situations. Chances are good that you know people who provide examples of each of these traits. **Personality traits** are stable characteristics or qualities that people show in a variety of situations over a long period of time, even a lifetime. They describe our tendencies to act in a particular way.

personality traits tendencies to behave in certain ways that remain relatively constant across situations.

TABLE 12.3

Which Trait Best Describes You?
Source: Adapted from Waugh, M. H., Hopwood, C. J., Krueger, R. F., Morey, L. C., Pincus, A. L., & Wright, A. G. (2017). Psychological assessment with the DSM–5 Alternative Model for Personality Disorders: Tradition and innovation. *Professional Psychology: Research and Practice*, *48*(2), 79.

Friendly	Kind
Self-confident	Undemanding
Tricky	Introverted
Unsympathetic	Iron-hearted
Distant	Crafty
Meek	Firm
Unargumentative	Outgoing
Tender	Nervous

Curious	Shy
Calm	Unsophisticated

The area within personality psychology that focuses on traits is called, not surprisingly, the trait approach. Trait researchers are interested in cataloguing traits and determining how many are needed for an adequate picture of human diversity. From this point of view, the traits that individuals possess (how many and to what degree) determine their personality. Thus, personality traits are said to be *dimensional*. This means that trait terms define spectrums that traits can be found along, ranging from people displaying very little to a lot of trait-consistent behaviour. Most traits don't emerge full-blown—they develop gradually over time. Some personality psychologists believe personality is not completely formed, or crystallized, until the late teens all the way to the early thirties, depending on an individual's experiences (McAdams, Shiner, & Tackett, 2018; Wolff, 2017). But this doesn't mean that traits are necessarily carved in stone. We all have the ability to modulate or change our behaviours over time. This may be difficult in extreme cases, but, for instance, very shy people can greatly reduce their shy behaviour, and vice versa (Zimbardo, 2018; Zimbardo & Radl, 1999). However, drastic changes may come at a cost. Shy people who act in an outgoing, extroverted way may have to decompress afterwards by finding some time alone (Little, 2015, 2008). A small price to pay, perhaps, for behaviour that people find rewarding in the long run. It was Socrates who said, "Know thyself." But how? Personality assessment techniques can provide us with some answers to this important question and we will have a detailed look at them a bit later in this chapter but first we will look the related question of how many traits a trait theory needs in order to properly describe and predict social behaviour.

Personality Traits: How Many Do We Need?

All modern, scientific inventories of personality are based on a trait model, The most widely used one today has five trait dimensions and, no surprise, is called the five-factor model (FFM) and will be discussed in detail in the section of Personality Assessment. Even the very first personality tests from as far back as the ancient Greeks were based on some trait theory or model. A **personality trait model** is a mini-theory about the structure of personality traits. It provides answers to questions such as, "How many traits and which ones?" As the name suggests, the FFM resolves these questions with the magic number "5." With all the attention the FFM has received, you might think it was the only one in use, but this is not the case. It *is* true, however, that the Big Five (yet another FFM name) has had a *big* impact on all of personality psychology and beyond, into clinical, social, and business areas of psychology (Seibert & DeGeest, 2017; Feher & Vernon, 2020). This is because it overlaps with many of the other trait models in use and thus has become a kind of unifying standard or benchmark for the field. Where did it come from? Are there other important models?

> **personality trait model** a mini-theory about the structure of personality traits.

Like all good psychological theories and models, the FFM has a long and storied history behind it. The FFM evolved out of a three-trait model, which in turn grew out of a 16-trait

model. And how many traits were there to begin with? Would you believe 27,000! It's not only interesting to see where they all came from but also to see how that huge pool of traits was reduced to something manageable and useful, like five, or even two or three.

It was a Harvard personality psychologist named Gordon Allport (1897–1967), back in the 1930s, who first got the ball rolling in the FFM direction. Rather than have one or two psychologists engage in "armchair theorizing" to come up with a pool of traits, as was common at the time, Allport had another idea about where to find them. He started with a full-sized (unabridged) dictionary. His idea, which we now call the **lexical hypothesis**, was that all the important (and not so important) ways that people can differ have already been encoded in our language and should be available from a comprehensive dictionary. So, with an open *Webster's New* (1924) *International Dictionary* taking up practically his whole desk, Allport began his painstaking search for unique trait terms. In his words, he was looking for terms that could "distinguish the behavior of one human being from that of another" (Allport & Odbert, 1936, p. 24). When the task was complete, close to 18,000 trait terms had emerged from Webster's dictionary, and by the late 1960s other researchers had brought that total to 27,000 (Allport, 1966). After removing unused (archaic) and derivative traits, the total shrunk to about 10,000. But still a long way to go to get down to five! What was needed was a statistical technique to help sort all of these traits into meaningful categories, and a powerful computer to do the calculations. Although data reduction statistical methods, along with mainframe computers, were under development in the 1930s, they remained primitive and impractical for a long time.

> **lexical hypothesis** the idea that our language contains the important ways in which people can differ.

Researchers had to wait almost a couple of decades to reach and jump the next hurdle along the road to the FFM. In 1952, a personality psychologist named Raymond Cattell published a book (Cattell, 1952) on a statistical technique called factor analysis (FA). FA is a mathematical procedure that allows the user to reduce a large number of variables, say, 10,000 trait words, into a manageable few. It is based on calculations of the *intercorrelations* among the trait words. The goal is simplification—to reduce a large set of traits into a small number of clusters, called *factors*. Similarity among traits is determined by the interrelationships that are revealed through their pattern of correlations. Highly positively correlated clusters of traits are lumped together into factors. Ideally, you would be left with a small set of factors that can be used to represent all the rest. For example, if people who rate themselves as, say, *friendly* also tend to rate themselves as *outgoing* and *cheerful*, perhaps a term like *extroversion* can be used in their place. High intercorrelations among a group of traits indicate they are all really tapping different parts of the same thing. What is this *thing*? In this case the point is that maybe all of these traits can best be subsumed under the heading of *extroversion*, which brings together the more specific personality descriptors that can be used to help define it. Factor analysis can also be used to help answer the question: Which of friendly, outgoing, *and* cheerful is more important in defining extroversion*?* It may be that friendliness is closer to the core of extroversion than cheerfulness. That is another empirical question that factor analysis can help answer.

Cattell used his factor analysis tool to reduce the 10,000 traits he found in his dictionary to

just 16 traits. Now that is data reduction! The factor analysis tool seemed invincible. Armed with his 16 traits (which he called source traits, because they were the source of all the other traits), like *dominant*, *trusting*, and *relaxed*, Cattell developed a questionnaire and set out to assess the world (Cattell & Mead, 2008). (See photo.) The questionnaire was appropriately named the 16 Personality Factors inventory (16PF) and has been widely used from its inception, but it is not without its critics. The major problem they point to is the fact that the 16 source factors are more intercorrelated (overlapping) than they should be (Bahner & Clark, 2020; Matthews, 1989). When factors such as source traits overlap, this suggests that one or more is unnecessary and thus could be dropped or folded in with another trait.

Baerbel Schmidt/Getty Images

Spotting the source traits **The fundamental dimensions of personality cited in the five-factor model and other theories of personality including the 16PF are each on display in this photo of people passing through an airport waiting area. Can you identify examples of these key trait categories?**

Evidence for trait overlap in the 16PF led one researcher, Hans Eysenck (1916–1997), to take another look at the inventory. His factor analysis, employing newer techniques designed to reduce overlap, yielded three independent (non-overlapping) **superfactors**: *extroversion* (sociable), *neuroticism* (worried), and *psychoticism* (nasty). Eysenck referred to them as *primary* dimensions of personality (Eysenck, 1973; Revelle, 2016). Drawing an analogy to primary colours and how they can be used to recreate all possible colours, he argued primary traits could be used to account for all possible traits (see **Figure 12.2**). Eysenck proposed a biological explanation for the importance and functioning of his

primary traits, which we will return to in a later section. Not everyone agrees, however, with Eysenck's choice of "primary" traits. Some researchers (e.g., Costa & McCrae, 2017, 1986) took issue with Eysenck's use of psychoticism, because psychoticism test items (e.g., "likes to tease puppies") thankfully do not apply to many people in the population. Positive Psychologists have actually shown, though, that training people to find opportunities for humour can reduce these sorts of negative personality tendencies (see Positive Psychology 12.2). Nonetheless, Eysenck's model has been one of the most researched in the history of modern personality psychology (especially the variety of *extroversion* he proposed) and is closely aligned with the Big Five model. In fact, the first marketed Big Five instrument, called the NEO, was designed to correct the "psychoticism problem" of Eysenck's model (Costa Jr. & McCrae, 2017). If you are getting the impression that factor analysis isn't quite the objective technique you initially thought it was, you would be right. Debates about its use continue (Prudon, 2015; Kline, 2014).

> **superfactor** a fundamental dimension of personality made up of a related cluster of personality traits.

Another technical issue in the literature has to do with whether three factors are enough. The jump down from 16 to three factors was viewed as an extreme move by some (Friedman & Schustack, 2016; Schultz & Schultz, 2016; Wiggins & Trapnell, 1996), and one not justified by most factor analytic studies. Too much trait information was lost in the translation, it was argued, and if psychoticism were dropped (as most agreed it should), this would only make matters worse through oversimplification. Although the debate may now be all but over, it is interesting to note the family resemblance between Eysenck's model and the Big Five. Two of Eysenck's three traits are there in name (extroversion and neuroticism) and psychoticism, the nastiness trait, may be viewed as just an extreme reversal of the agreeableness trait (Lopez et al., 2020; Heaven et al., 2013).

As often happens in polarized debate, a solution lies somewhere in the middle. After many decades of fine-tuning the factor analytic approach, many researchers have now agreed that the number five, if not magical, seems optimal in this case. What convinced many was the fact that people's ratings on hundreds of traits collected in many parts of the world, regardless of the language used, yielded the same five basic dimensions. It strongly appeared that a universal structure of personality had been found (McCrae, 2017). Some researchers, such as Kiboem Lee at the University of Calgary, argue that at least one more factor is needed to account for the variations in human personality. Lee and his collaborator Michael Ashton argue for considering honesty and humility as related and important aspects of personality and social functioning (Lee & Ashton, 2013). Although some theorists argue that factors should be added to the list of five, a great many researchers believe that individual differences in personality can indeed be captured by the five broad categories of this theory (Widiger, 2017; McCrae & Costa, 2003). Because of the theory's popularity with researchers, a significant body of relevant research has accumulated (Zuckerman, 2012, 2011; Widiger, 2017). Five may be the universal number when referring to cross-cultural consistency in personality dimensions, but models with fewer (or more) than five basic dimensions can still be very useful. Moreover, having only two or three factors in a model does not mean you are limited to talking about only two or three traits.

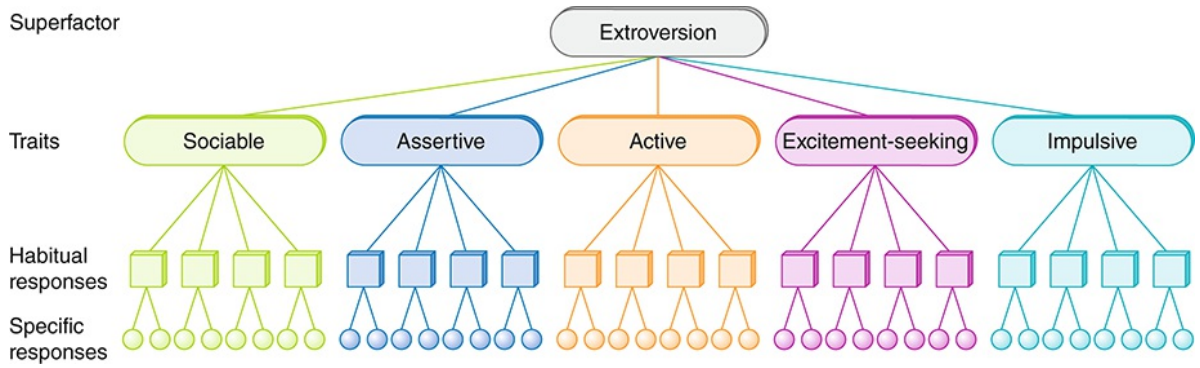

FIGURE 12.2 Eysenck's model of personality **Eysenck used factor analysis to identify traits that cluster together. He described three basic trait clusters, which he called superfactors. Each superfactor, such as extroversion shown here, is made up of specific traits, and in turn each trait is made up of habitual and specific responses.**

12.2 Psychology Around Us | Positive Psychology

Personality Traits and Humour Training

Humour training is one of the hot new topics in positive psychology. Incorporating humour into our lives can give us a much-needed break from stress, and some studies have shown it can even help us learn (McCabe, Sprute, & Underdown, 2017). Humour training has been used to minimize the effects of mild depression and enhance happiness. It has been shown to enhance subjective well-being and overall health (Ruch & McGhee, 2014). A recent study has shown a positive relationship between humour and our ability to deal with the negative effects of making mistakes in life (Fischer, Carow, & Eger, 2020). This study found that using humour when dealing with or handling mistakes positively affected the health and well-being of the study's subjects. One question that has only recently been addressed by scientists, however, is whether a person's personality matters when it comes to the effectiveness of humour training.

Wellenzohn & colleagues (2018) gave subjects a set of humorous interventions and assessed whether changes in their scores for happiness increased and depression decreased. The novelty of their study was that the researchers also examined their participants' self ratings of the neurotic, extroverted, and psychotic aspects of their personality. What they found was that those with an extroverted personality type benefited the most from humour training when it came to changing their happiness. So, while humour training may benefit all of us, if you're an extrovert it may definitely be in your best interest to keep a bit of humour in your life.

Rawpixel.com/Shutterstock.com

The positive effects of humour **Humour training helps to increase everyone's levels of happiness but improves that of extroverts the most.**

Consider the model shown in **Figure 12.3**, called the **interpersonal circle**, conceptualized by Timothy Leary and developed by Jerry Wiggins at the University of British Columbia and Ross Broughton and Paul Trapnell at the University of Winnipeg. Here we find what appears to be another 16-trait model, with the traits arranged on the periphery of a circle. The traits are of a particular variety, called *interpersonal* traits, which have to do with things people do when interacting with others, like being shy or dominant. All of these interpersonal traits can be generated by the two primary dimensions labelled *nurturance* and *dominance*, on the *X* and *Y* axes in the figure, respectively. For example, *extroverted* can be viewed as a blend of high nurturance and high dominance (because you have to have high coordinates on the *X* and *Y* axes to get to the spot where *extroverted* is). Likewise, *trusting* can be viewed as a blend of high *nurturance* (high *X* axis) and low *dominance* (low *Y* axis), and so on for the other traits. In addition, the circle is used to convey the *interrelationships* of the traits in the model. The closer the traits are to one another on the circle, the stronger their relationship and the higher their (positive) correlation. The circle provides a powerful tool for interpreting interpersonal traits and other traits that may have some interpersonal (person-to-person) content (Gurtman, 2020; Barford, Zhao, & Smillie, 2015; Wiggins & Broughton, 1991; Trapnell & Wiggins, 1990; Wiggins, Phillips, & Trapnell, 1989).

interpersonal circle a two-dimensional personality trait model based on blends of dominance and nurturance.

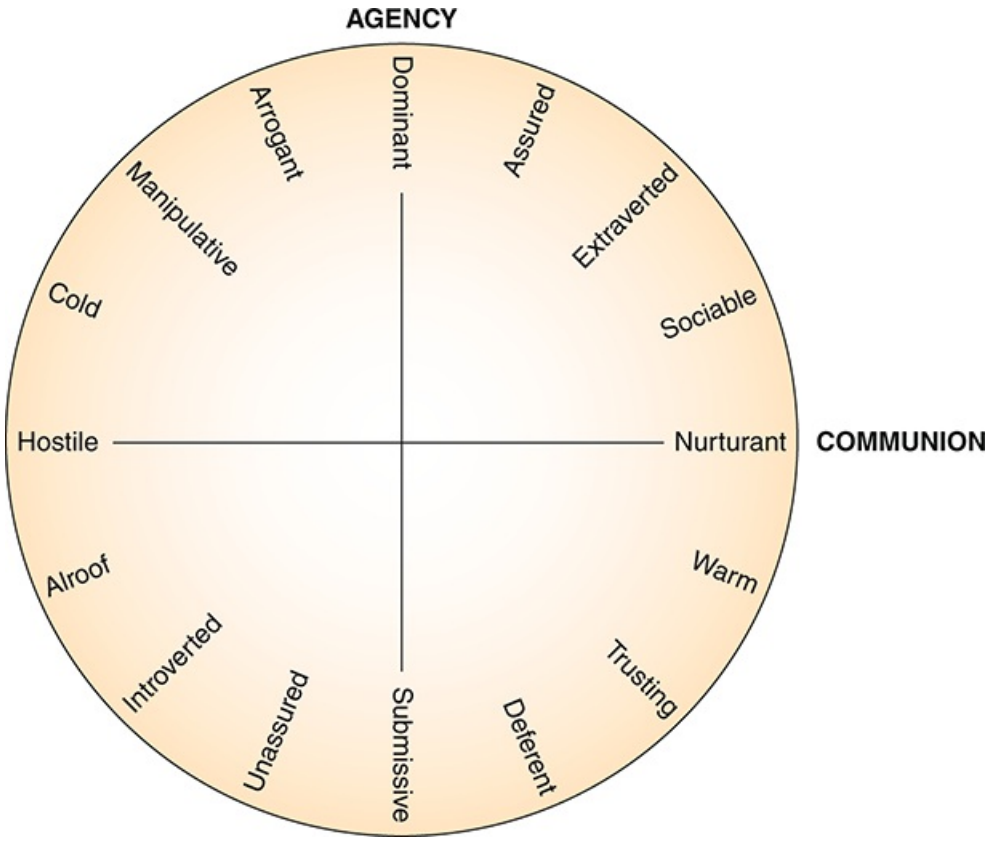

FIGURE 12.3 The Wiggins interpersonal circle of traits.

Another advantage of the interpersonal circle model is that it tracks the fact that how people present, or act, varies depending on who they are interacting with and the social contexts in which they are interacting. As originally suggested by Timothy Leary (1958) before he quit Harvard University and became a counter-culture guru advocating the use of LSD as a means of expanding one's conscious experience, the interpersonal circle model supports the idea that a healthy personality is not a fixed structure, but instead is a flexible one that shifts in ways that optimize the outcomes of social interactions. The model helps clinicians figure out how to get overly rigid clients, such as those who are dominant or domineering, get unstuck and become more flexible and responsive in their social interactions (Hopwood, 2018; Critchfield, Benjamin, & Levenick, 2015; Benjamin, 2002). As you will see, when we talk about personality disorders later in this chapter and in Chapter 15, rigidity or a lack of flexibility in personality areas can be quite problematic.

Evaluating Trait Theories

As we have noted, a number of questions have been addressed by research into trait theories. First, do traits apply to a variety of cultures? Eysenck found that his superfactors described basic types across a number of countries. In addition, there is growing evidence that people in many cultures display personality types that can be captured by at least three of the Big Five superfactors and sometimes by all five (McCrae, 2017; Bowden et al., 2016; Correa & Rogers, 2010).

A second question is whether traits, and the behaviours they produce, remain stable across

situations. The answer appears to be sometimes yes and sometimes no. In a classic investigation conducted in the early 1980s, investigators observed college students and rated their levels of *conscientiousness*, based on behaviours ranging from being punctual to completing assignments on time and tidying their rooms (Mischel & Shoda, 2010; Mischel & Peake, 1982; Mischel, Mendoza-Denton, & Shoda, 2002). The researchers found that levels of conscientiousness were relatively stable across *similar* situations, but not particularly consistent across very different situations. That is, persons who are punctual for class will likely be punctual for dates, because those situations and their demands are similar. However, individuals who are punctual may not necessarily keep their rooms clean. Although both of these situations require conscientiousness, the situations are quite different, leading to inconsistent displays of conscientiousness for some people.

A third question is whether traits, and the behaviours they dictate, are stable over time. Studies indicate that personality traits are more stable over a short period of time than over a span of years (Golsteyn & Schildberg-Hörisch, 2017; Donnellan, Hill, & Roberts, 2015). People who conscientiously show up on time for an appointment today are likely to be punctual for appointments next week and next month. But today's punctuality is not as likely to predict punctuality a year or two from now.

Similarly, traits often show inconsistency across a person's lifespan, especially as individuals grow from childhood to adulthood (Edmonds et al., 2013). For example, people who score high on the *openness* superfactor (adventurous, imaginative, and untraditional) during their teenage years may display less openness in their fifties. Researchers disagree on why such lifespan changes occur. Some believe that they reflect intrinsic, biologically based maturation while others hold that they have more to do with changes in an individual's social environment (Bleidorn & Hopwood, 2018; Specht, 2017). Either way, it is worth noting that once a person reaches adulthood, lifespan fluctuations seem to lessen, and traits become increasingly stable across the adult years (Harris, Humphrey, Migo, & Kopelman, 2016; Milojev & Sibley, 2014; Anusic & Schimmack, 2016).

Ableimages/Getty Images, Inc.

Another benefit of conscientiousness **An elderly teacher carefully demonstrates to a student how to operate woodwork equipment both safely and productively. Studies indicate that, on average, conscientious people live longer than less responsible individuals.**

Finally, the predictive value of a model is another issue of concern to researchers. Although trait theories do not necessarily claim to serve as a device for predicting what will happen in a person's life, it is tempting to apply them in this way. In fact, the idea that personality factors may be able to predict broad outcomes dates back many years. One longitudinal investigation found that the Big Five superfactor *conscientiousness* helps to predict the length of a person's life (Kern & Friedman, 2008; Friedman, Kern, Hampson, & Duckworth, 2014). (See photo.) In this study, a large number of children were followed for 70 years by several researchers. When the children were 11 years old, their parents and teachers rated them on various personality dimensions, and subsequent records were kept about these individuals and the causes of their eventual deaths. It turned out that, on average, those who had been rated as conscientious lived significantly longer than those who had not been rated as conscientious. To explain this finding, the researchers speculated that conscientiousness is related to a broad pattern of health-related behaviours, such as not smoking and not drinking—behaviours that add up over a lifetime. Similarly, research has suggested that certain personality attributes may be predictive of marital satisfaction. One study found, for example, that high agreeableness greatly increases the chances of having a happy and satisfying marriage (Abbasi, 2017; Donnellan, Conger, & Bryant, 2004), as do conscientiousness, emotional stability, and intellectual openness.

What Do You Know?

8. Who are Gordon Allport and Hans Eysenck, and what were their contributions to the trait perspective?

9. What is factor analysis, and how is it tied to trait theories?

10. How is the interpersonal circle model of personality organized?

11. How stable are traits over time and across situations?

What Do You Think? • Think of three famous people and predict how they each might score on the major trait categories of the five-factor model.

Personality Assessment

LEARNING OBJECTIVE 4

Describe the two major types of personality tests, and give examples of each.

Go to almost any pop-culture Internet site (for example, www.queendom.com) or flip open any newspaper or popular magazine and you will likely find evidence of people's desire to understand, describe, and use personality traits. Astrology, personality quizzes, and even clairvoyants offer personality-based analyses and advice to thousands of people worldwide. The fact that devices such as horoscopes have been shown repeatedly to be unreliable has done little to diminish their popularity (Mazur & Watzlawik, 2016; Fichten & Sunerton, 1983). Of course, there are also more formal tools for assessing personality, and these tools are used in a variety of important contexts. Clinicians use personality assessment tools, including projective tests, which are discussed later in this chapter, to learn more about their clients' problems. Researchers may use them to conduct personality research or to help select participants for their studies. Employers, job counsellors, and industrial organizational psychologists often use such tools to maximize rates of retention of the most productive employees (Li, Barrick, Zimmerman, & Chiaburu, 2014) or to help their work teams function more effectively (Guchait, Hamilton, & Hua, 2014). For a look at the applications that industrial/organizational psychologists make of the trait approach to workplace settings, check out the Psychology@Work video on Individual Differences. Scores on traits such as conscientiousness have, for example, been used to predict absenteeism, misconduct, and termination (Wilmot & Ones, 2019). The personality tests used most frequently by these professionals are personality inventories, while some clinicians use projective tests, which will be discussed later in this chapter.

Video **PSYCHOLOGY@WORK**

Individual Differences This video looks at the ways in which

industrial/organizational research and practice applies the assessment of individual differences to workplace settings and touches on the ethical implications of diversity in relation to these activities.

Personality Inventories

You have very likely taken a personality inventory at some time in your life. **Personality inventories** are questionnaires that require individuals to respond to a series of true–false or agree–disagree statements designed to measure various aspects of personality. These types of assessments are called self-report inventories because they depend on information that respondents supply about themselves.

> **personality inventory** a questionnaire designed to assess various aspects of personality.

For the general public, today's most widely used scientific personality inventories, used by researchers and practitioners alike, are based on a personality theory and model called the **five-factor model** (FFM) (Widiger, 2017; Wiggins, 1996). The five traits of the FFM (see figure 12.3) are: *openness to experience*, *conscientiousness*, *extroversion*, *agreeableness*, and *neuroticism* (see **Figure 12.4**). The FFM is sometimes referred to as the OCEAN of personality, to signify its wide coverage and application. (Tip: OCEAN is also a useful acronym to help remember the five traits.) The most popular FFM inventory is the *Revised NEO Personality Inventory* (NEO PI-R) (Costa Jr. & McCrae, 2008). Another widely popular personality inventory for the general public is the Myers-Briggs Type Indicator (MBTI) (Myers, 1962), which is based on Jung's writings about personality and is typically used by businesses to understand personality dynamics in workplace settings. The MBTI is used as a catalyst to get people within organizational teams and groups talking about their social interactions, but it lacks the validity required of inventories used to make hiring and promotion decisions (Moyle & Hackston, 2018; Emre, 2018). Interestingly, the most widely used personality test by all kinds of psychologists is one developed not for the general public but for abnormal populations, called the Minnesota Multiphasic Personality Inventory 2 (MMPI-2) (Butcher et al., 2015; Butcher, 2001). A person's responses on this test are used primarily to assess psychological disorders (discussed in Chapter 15). The items on this test were selected much differently than the other tests we mentioned. They were not selected according to any theory or model. MMPI items were *empirically* derived (Williams, Butcher, & Paulsen, 2019). This means that many possible test items were administered to groups of people with various personality styles and psychological disorders, and their responses were analyzed to determine which items had predictive value and which patterns of responses corresponded to particular personality styles and diagnostic groups. It is important to note that the test questions do not necessarily have to make intuitive sense but are instead kept on the test if they have predictive value. For example, if most people who score high on extroversion choose green or depressed people choose black as their favourite colour, then the question, "What is your favourite colour?" has predictive validity and would remain on the test, even though it is not clear at this time, *on the face of it*, what "green" has to do with personality, though black does seem to make some sense in relation to depression. It is in this sense that empirically derived test items

may lack face validity even though they may possess predictive validity. Interestingly, tests having both face *and* predictive validity tend to be more accurate overall (Kreis et al., 2012; Broughton, 1984).

five-factor model an empirically derived trait model that proposes five major trait categories: agreeableness/disagreeableness, extroversion/introversion, neuroticism/stability, conscientiousness/irresponsibility, and openness to experience/unimaginativeness.

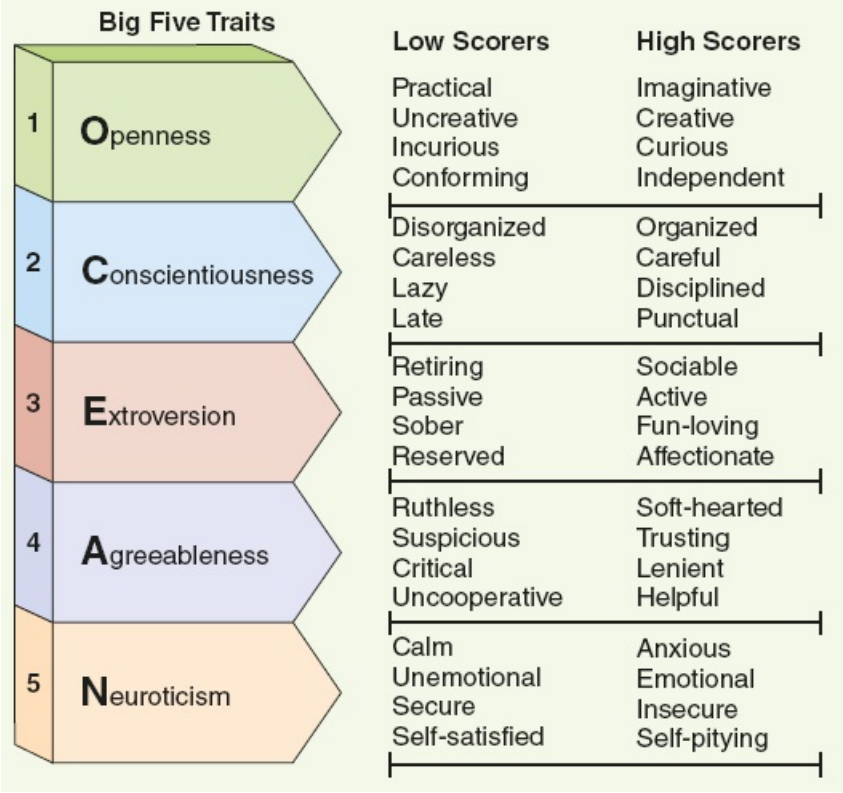

FIGURE 12.4 The five-factor model of personality Studies using factor analysis have identified five broad categories of traits, known as the Big Five. Many researchers believe that individual differences in personality can be captured by these five categories.

Image Source/Corbis Images

Personality quizzes **Personality inventories are more carefully put together in terms of reliability and validity than the personality quizzes in magazines.**

Despite the popularity of personality inventories, concerns have been raised about their use as accurate indicators of personality. Some researchers say the tests, which rely on self-reports, may not always be accurate (e.g., Spaans et al., 2017). Also, if we are not fully aware of our own behaviour patterns, preferences, or interests, our self-reports may not reflect our actual personality. Most researchers in the personality area say you can avoid these criticisms by properly validating self-report tests with behavioural measures. For example, Costa and McRae (2010) have found that those scoring high on the NEO PI-r conscientiousness scale receive higher supervisor ratings at work, are generally more punctual for class and appointments, and are more likely to complete their university degree, among other findings.

Another concern is that personality tests may not always be used and applied properly. Some employers, for example, use measures of conscientiousness to predict an applicant's potential job performance because, as mentioned, they are quite effective predictors of that type of performance. But some jobs are not well suited for conscientious people, at least not overly conscientious people (Sulea, Fischmann, & Filipescu, 2012; Hogan & Ones, 1997). As well, openness to experience (finding new ways to do things), in addition to conscientiousness, adds to performance when the job is complex (Blickle et al., 2013; Wiersma & Kappe, 2016).

Still another concern is that test-takers may tailor their answers on personality inventories to try to create a good impression—a phenomenon known as **socially desirable responding** (Viswesvaran & Ones, 1999). For example, the adjective "unintelligent" is a very undesirable trait term. It is so undesirable that on one popular personality test, this item, for over 40 years, was never endorsed by anyone! On the other hand, "intelligent" is almost always highly endorsed (Gough & Heilbrun, 1983). So on the basis of their extreme social desirability standing (never endorsed versus always endorsed), these two items, and items like them, are not good test items because they have no predictive validity—they are

virtually the same for everyone. Delroy Paulhus (Bensch, Paulhus, Stankov, & Ziegler, 2019; Paulhus, 2017, 2012), at the University of British Columbia, has studied this topic extensively and has shown that the way to control for social desirability on personality tests is to use items that are relatively equal in their social desirability standing. The problem of socially desirable responding was also anticipated by the creators of the MMPI. They included certain questions, called *validity items*, in the questionnaire to assess the likelihood that a respondent would purposely give an answer that was socially desirable rather than accurate. Suppose, for example, that an individual keeps answering "true" to such items as "I smile at everyone I meet" and "false" to "I get angry sometimes." It is assumed that these responses, and perhaps many others as well, are instances of socially desirable responding because it is highly unlikely that such a respondent is in fact a perfect saint (unless you are another Mother Teresa). In such cases, test scorers may disregard or adjust the respondents' personality scores.

socially desirable responding tailoring answers on personality inventories to try to create a good impression.

The use of personality tests as part of organizational hiring processes has a long history. However, early personality tests were not demonstrated to be particularly good (reliable or valid) at predicting who the best candidate for a job would be. As a consequence, in the United States there were a number of successful lawsuits claiming that hiring decisions based on older personality tests were unfair (Youngman, 2017; Rothstein & Goffin, 2006). In Canada, there was much less litigation. Currently, there are a number of better-designed personality tests that do, in fact, meet legally defensible criteria for use as pre-employment selection tools (Youngman, 2017; Rothstein & Goffin, 2006). The use of such tests in Canada is regulated by bodies such as human rights commissions, which limit the types of personal information employers can ask prospective employees to questions (including personality test questions) that are directly relevant to the job for which they are applying. Tests must be carefully constructed to ensure they meet these criteria and also show appropriate levels of reliability and validity (Kline, 2015).

Projective Tests

Projective tests are quite different from personality inventories (see **Figure 12.5**). These tests are commonly used by psychoanalytic clinicians and researchers and are intended to tap into a person's unconscious mind to detect personality styles and conflicts hidden beneath the surface. The most widely used and famous projective test is the *Rorschach Inkblot Test*. During the test, participants are presented with a set of 10 inkblots and asked to explain what they see. The ambiguous shapes of the inkblots are intended to force participants to *project* structure and meaning onto the images, and the participants' responses are thought to reveal underlying psychological themes and personality issues. For example, a person who sees images of animals or weapons in the inkblots is often thought to be grappling with underlying aggressive urges.

projective test a personality assessment device intended to tap a person's unconscious by presenting the person with an ambiguous stimulus and asking the

person to interpret what the stimulus means.

Some clinicians believe that the Rorschach test provides useful suggestions that can enhance the effectiveness of assessment and therapy or guide forensic assessments (Di Nuovo & Castellano, 2016; Tibon-Czopp & Weiner, 2016). It is widely agreed in the scientific community, however, that projective tests, such as the Rorschach, display low validity, or accuracy (Smith et al., 2018; Riley, Combs, Davis, & Smith, 2017; Kleiger, 2016). Scoring of the tests depends heavily on interpretations by the test administrators—interpretations that may be affected by the assessor's professional biases or level of expertise. In addition to problems with validity, many have concerns about the reliability, or consistency, of projective tests. Studies have shown that individuals who take a Rorschach test today may offer responses that are very different from those they offered when they took the test last week, leading to different personality assessments. Look again at the sample in **Figure 12.5**. You can probably see why the Rorschach test might present difficulties.

An alternative and commonly used type of projective test is the *Thematic Apperception Test (TAT)*. This tool, created in the 1930s by psychologist Henry Murray (1943), is made up of ambiguous black-and-white drawings of people in various situations. Test-takers are asked to describe and make up a story about each drawing. The uses and criticisms of the TAT are similar to those of the Rorschach. Although some systematic scoring procedures exist, most clinicians rely on their own judgments when analyzing an individual's TAT responses (Piotrowski, 2017; Jenkins, Dobbs, & Leeper, 2016). Additionally, it is difficult to know for certain that the stories created by individuals reflect how they are actually feeling; they may instead represent the individuals' projections of how they believe they should be feeling (McCredie & Morey, 2019).

13. What factors make up the Big Five model?

14. What is socially desirable responding and how is it addressed in the MMPI-2?

15. What are some problems with projective assessment techniques?

What Do You Think? • There are so-called personality tests all over the Internet. Which ones have you come across? Why are most such tests uninformative and often misleading?

The Situationist and Interactionist Perspectives

LEARNING OBJECTIVE 5

Describe and differentiate the situationist and interactionist views of personality.

In terms of the big picture question of where personality comes from, we have looked at theories like Freud's that put a lot of weight on inherited instincts, with some parent–child interaction to trait approaches that also lean toward factors such as temperament that influence how we come to present ourselves socially through or personality profiles. However, an obvious question concerns the extent to which our personalities are formed by the situations or circumstances in which we find ourselves. Walter Mischel (2004) took a strong stance against the general idea that personality is largely made up of internal traits and instinctual factors and, instead, argued for the importance of situational factors in shaping and directing human behaviour. If you think back to the theories we covered in Chapter 7, you will have guessed some of the other psychologists who have looked closely at the role of situational influences on personality.

The Situationist Perspective

Situationist theorists acknowledged that personality factors come into play when people are making choices, reacting to events, or displaying other behaviours. Nevertheless, the theorists argued, situational "pushes" and "pulls" rule in most instances.

The behaviourist B. F. Skinner, discussed in Chapter 7, could be said to have viewed personality from a situationist perspective. Indeed, Skinner believed that human behaviour was completely shaped by environmental factors. What we call *personality*, Skinner saw as simply a certain consistency in what he called *response tendencies*. By that, Skinner meant that we approach life in a certain way because some of our behaviours have been rewarding to us in the past while other behaviours have not. That is, we tend to favour, or

repeat, responses that have previously helped us gain a desired outcome or avoid an undesired one. Whereas a trait theorist might look at your presence in college or university as some combination of intelligence, conscientiousness, and perhaps a little neuroticism, Skinner would have said that you studied because you found academic achievement to be rewarding or because studying served to keep your parents happy. Because these outcomes were sufficiently motivating, you developed a general response tendency to persist at studying, which led you to respond consistently and successfully in academic situations (Evans, 1968).

Caiaimage/Robert Daly/Getty Images

Situationism **Situationism is a view of personality that notes that in many social situations, such as a surprising scene in a play, people respond in fairly similar ways, meaning that the situation drives their response rather than their personality.**

Situationism has a strong appeal. As we already mentioned, human beings appear predisposed to explain their own behaviour in situational terms, although they tend to explain others' behaviour in terms of traits. How often have you responded "it depends" when somebody has asked how you would handle a situation? (see photo). Certainly, we do not like to think of ourselves as "trait machines"—robots who behave as if we were preprogrammed.

situationism a view of personality, which notes that in many social situations people respond is similar ways, meaning that the situation drives their response rather than their personality.

At the same time, however, we must note that there really can be no such thing as *pure* situational factors in human behaviour (Ewen, 2014). Consider, for instance, Skinner's

perspective on reward. As you saw in Chapter 7, Skinner defined a *reinforcer* as something that leads you to engage more often in a particular behaviour. In other words, what is a reinforcer to you may not be a reinforcer to someone else. Ultimately, even as we acknowledge the power and influence of situations, we must acknowledge the power and influence of people and their personalities; if not, we have trouble arguing about the importance or even the possibility of ethics or the personal management of our social behaviour (Bates & Kleingeld, 2018; Miller, 2017). Thus, it is not surprising that many situationist theorists, including Walter Mischel, the perspective's early leader, came to believe that the most appropriate models are those that try to integrate both personality variables and situational factors to explain behaviour, eventually moving to an interactionist perspective of personality.

The Interactionist Perspective

Interactionism focuses on interactions between people and situations. At the centre of the interactionist model is the idea that people influence the situations they encounter. According to this model, the choices you make, such as attending your present college or university or being enrolled in your present classes, are functions of underlying personality traits. Let's say, for example, introversion leads you to choose a school with really small classes—a choice that you suspect would make it more comfortable for you to participate in class—or a school with really large classes—a choice that you believe would make it easier for you to go unnoticed in class. Such choices are likely to result in self-fulfilling prophecies. If you choose the school with big classes, for example, the large class sizes will indeed help ensure that you can remain quiet in class and continue your introverted style. This idea that individual and situational variables interact suggests a way of moving beyond the trait-versus-situation controversy.

> **interactionism** a view emphasizing the relationship between a person's underlying personality traits and the reinforcing aspects of the situations in which they choose to put themselves.

One of the leading interactionist theories is cognitive psychologist (and Mundare, Alberta-born) Albert Bandura's *social-cognitive theory* (Bandura, 2016, 2008, 2006, 1986). Bandura is famous for introducing the concepts of modelling and self-efficacy to the study of human behaviour and personality. As you will recall, *modelling*, also known as *observational learning*, is a process by which people, especially as young children, learn to respond to particular situations by observing and imitating the behaviour of others. *Self-efficacy* refers to people's personal beliefs about their ability to achieve the goals they pursue. The higher your self-efficacy, the more likely you are to pursue a goal and, ultimately, to be reinforced by the outcome of your efforts (Locke & Latham, 2019; Levack et al., 2016).

How do these concepts influence personality? Through a process Bandura called *reciprocal determinism*. In Bandura's way of thinking, the external environment, internal mental events (such as one's beliefs and expectations), and behaviour all interact with one another. How, for example, might your current presence in college or university be explained? Bandura might note that as a child you observed your parents or friends studying or working hard, and as a result you engaged in similar behaviour when you entered the

school environment. Perhaps you were praised by teachers or your parents for good grades, which reinforced that behaviour (see photo). You may in turn have developed a confident belief that you were a good student and curious about and open to new experiences, and your high level of self-efficacy may have led you to persist in behaviours (listening, completing your homework, studying) that further led to desired reinforcements (praise, good grades, positive self-image).

Stefan Dahl Langstrup/Alamy Stock Photo

Bandura's theory of reciprocal determinism **In Bandura's view, personality is determined by the interaction of the external environment, internal mental events, and behaviour. For example, receiving good grades and praise for schoolwork as a child may help you believe that you are a good student and this high level of self-efficacy may further lead to behaviours (studying and doing homework) that produce further desired reinforcement—more good grades and praise.**

The major advantage of this perspective over other theories of personality is that Bandura's theory, with its special emphasis on observable variables, such as models, behaviours, goals, and outcomes, is readily testable. There is a vast amount of data linking both modelling and self-efficacy to personality development and change across the lifespan (Adams et al., 2020; Huang, 2016; Alessandri et al., 2016; Mroczek & Little, 2014).

With an interactionist perspective in mind, some personality researchers uncovered a different kind of consistency in human affairs: not trait consistency, not situation consistency, but *disposition-situation* consistency, which seems to have useful implications for organizational (persons in organizations) psychology. They have discovered that interactive effects between dispositions (traits) and situations are common, and that disposition-situation relationships often show stability (Fajkowska, 2018; Furr & Funder, 2018; Lamiell, 2018; Tasselli, Kilduff, & Landis, 2018). Such stability would be reflected by the statement, "We can change our organizational culture in ways that will lead to positive changes in the levels of consciousness and competitiveness among our employees."

Before You Go On

(Answers to Before You Go On may be found online in the Course Resources.)

What Do You Know?

16. What is the situationist view of personality, and what theorists played key roles in promoting it?

17. What is the interactionist view of personality, and how does Bandura's social-cognitive theory fit into this perspective?

What Do You Think? • How might Skinner and Bandura each view someone's failure to quit smoking?

Biological Foundations of Personality

LEARNING OBJECTIVE 6

Discuss the heritability of personality traits and some of the neural systems that may be involved in the expression of personality.

You saw earlier that the trait-versus-situation debate has moved toward an interactionist view. As we mentioned, the traditional nature–nurture debate has changed in much the same way. In recent years, many researchers have been trying to understand the *relative* contributions of genetic and environmental factors to the development of personality. Other researchers have been investigating what brain structures and other neurological factors affect personality patterns. Let's see what they have found.

T.K. Wanstal/The Image Works

Separated at birth **Identical twins Gerald Levy and Mark Newman were separated at birth and did not meet or know of each other's existence until adulthood. In the**

interim, they had both become firemen and developed a range of very similar personality characteristics, mannerisms, interests, and hobbies.

How Much Do Genetic Factors Contribute to Personality?

As we have seen throughout this book, situations in which twins are separated very early in life and raised in different families afford researchers a unique opportunity to study the separate effects of genetics, shared family and social environments, and non-shared environments. Perhaps the most famous of these twin adoption studies is the *Minnesota Study of Twins Reared Apart* (MISTRA) (Wilson et al., 2019; Segal, Montoya, & Becker, 2018; Joseph, 2014). This investigation focused on 59 pairs of identical twins who had been raised in different families and 47 pairs of fraternal twins raised in the same household. Recall that identical twins have exactly the same genetic structure, while fraternal twins are no more genetically similar than non-twin siblings.

The twins who participated in the study spent six days taking personality and intelligence tests. The identical twins proved to be substantially more similar on every psychological dimension than the fraternal twins, even though the identical twins had been raised in separate homes and families. These results suggest that shared environments are less important than genetic factors to the development of temperament and many personality traits, although shared environments certainly do contribute (Bouchard Jr., 2016; Segal, 2012). (See photo.)

Some broad traits appeared to have particularly strong genetic links (see **Figure 12.6**). For example, in twin studies of personality, the superfactor *agreeableness* from the Big Five scale had an estimated heritability coefficient of .40, and the heritability coefficient (which ranges from 0 to 1.0) of the superfactor *openness* was estimated to be .55 (Young et al., 2019; Bouchard, 2004). Among more specific traits, the heritability coefficient for *warmth* was estimated to be .23, while that for *excitement* was estimated to be .36 (Feist, 2019; Jang et al., 1998).

Some researchers have suggested that certain behavioural tendencies, which are expressions of personality, may also have an inherited component. For instance, genetic factors may contribute to an individual's tendency to watch television (Huppertz, de Geus, & van der Ploeg, 2018; Prescott, Johnson, & McArdle, 1991). Even more complex behaviours, such as the tendency to get a divorce (Salvatore et al., 2017) and to develop alcoholism (Chassin, Colder, Hussong, & Sher, 2016; Froehlich, Zink, Li, & Christian, 2000), have been found to be partially heritable. Of course, no single gene is at work in traits or in behaviours such as these. More likely, multiple genes interact and affect an individual's broad biological systems, and these systems contribute to the traits or behaviours in question.

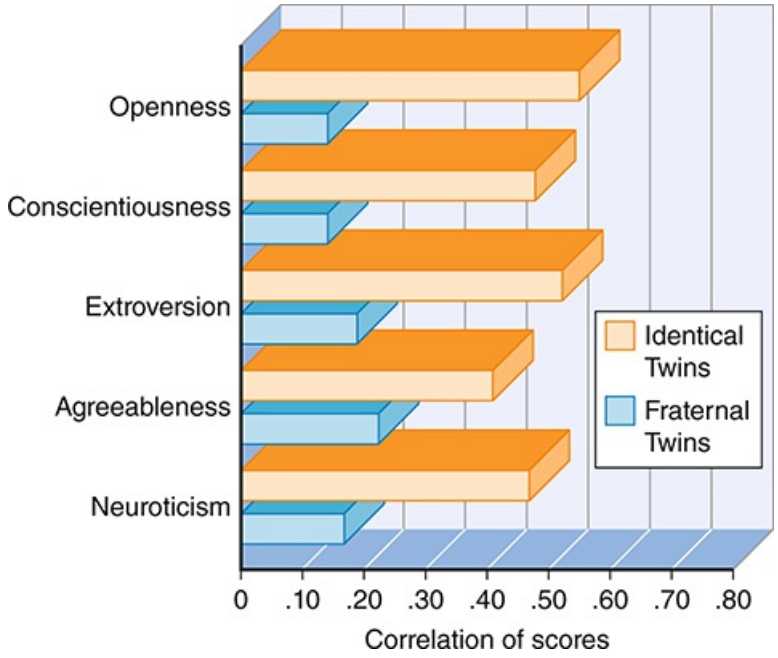

FIGURE 12.6 Heritability of the Big Five traits among twins Studies comparing identical twins (who share 100 percent of their genes) and fraternal twins reveal that the Big Five personality traits have a strong genetic component (Loehlin, 1992).

The media has embraced the Minnesota Twin Study for its straightforward findings. It is easy, though, to misinterpret the meaning of heritability statistics. Based on their findings, for example, the study's authors estimated that the *heritability coefficient* of IQ is close to .70 (other studies suggest that it is closer to .50). Does this mean that IQ is 70 percent genetic and 30 percent environmental? No. As noted in Chapter 10, the heritability coefficient is related to the total variance in a population, not to the variance within a given individual. That is, a heritability coefficient of .70 means that 70 percent of all differences observed in the tested *population* are due to genetic factors rather than to environmental differences.

Whatever the genetic pathway, even strong proponents of a genetic model recognize that environmental experiences also play a critical role (Zuckerman, 2012, 2011; Wahlsten, 2016). Recall that Eysenck considered personality traits to be biologically based and proposed that the superfactor *psychoticism* served as a marker of psychotic tendencies, such as schizophrenia. Even Eysenck, however, discovered that persons who are predisposed to high levels of psychoticism will not necessarily develop schizophrenia. Their environmental experiences help determine whether they will become disabled by their genetic disposition or channel that disposition into more productive behaviours.

Personality and the Brain

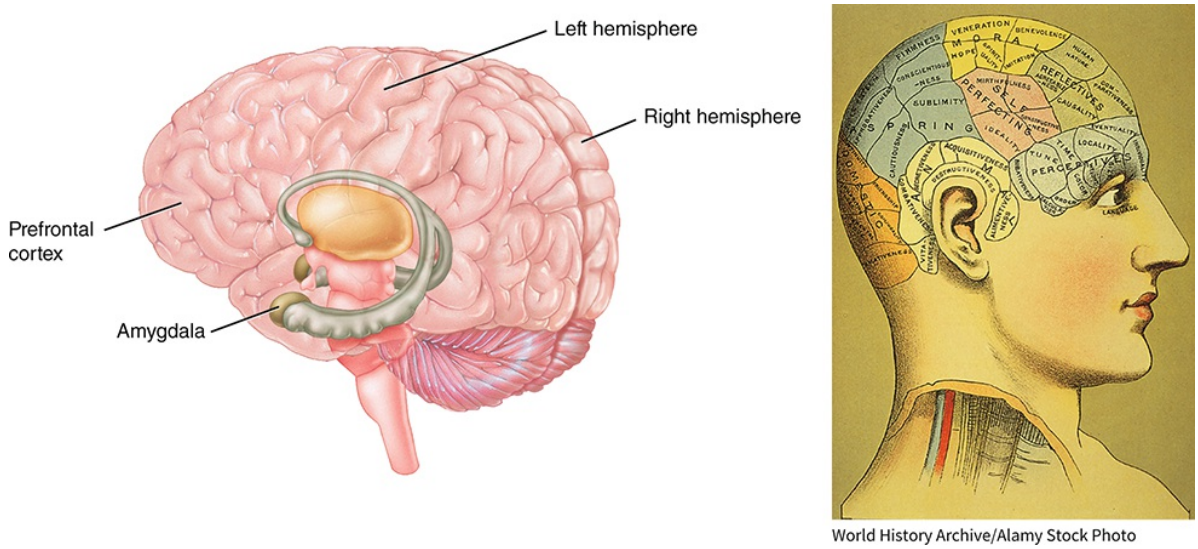
Twin studies, as we have seen, suggest links between genes and personality. But these studies do not provide precise information about what biological systems affect personality patterns. The search for such systems dates back to Franz Joseph Gall (1758–1828). Gall developed the theory of **phrenology**, a method of assessing a person's mental and moral qualities by studying the shape of the skull. He believed he could pinpoint specific parts of the brain that were responsible for distinct personality qualities by feeling the bumps they raised on the skull (see **Figure 12.7**). The practice became quite widespread between 1820 and 1850 (Gall, 1833).

> **phrenology** a method of assessing a person's mental and moral qualities by studying the shape of the person's skull.

While Gall's techniques were later shown to be inaccurate, his ideas about the localization of brain functions and the role of the brain in personality continue to influence neurological science (Rooney, 2017). Many researchers are currently attempting to uncover how brain structures, neurotransmitters, and other factors influence personality (Montag & Davis, 2018; Dubois et al., 2017; Deris et al., 2017; Kernberg, 2016). Much of this research focuses on specific personality traits, but a new line of study is also examining higher-order personality variables, such as moral inclinations and self-concept (Farb, Desormeau, & Dinh-Williams, 2016).

Research on Neural Systems and Personality

Many studies suggest that certain *brain structures* help to regulate personality. As we have observed in previous chapters, the amygdala, a structure in the limbic system, plays a key role in emotionality, motivation, and the processing of negative stimuli, especially stimuli that activate fear and avoidance responses (Bigot et al., 2020; Gothard, 2020). Brain imaging studies have shown that people with damage to the amygdala have difficulty becoming conditioned to fear stimuli (Feinstein et al., 2013; LeDoux, 1999, 2017). The damage may prevent the amygdala from responding to stimuli that normally excite fearful responses in people without amygdala damage. Such studies have spurred a number of psychologists to theorize that children who display an inhibited personality—characterized by shyness and fear of the unfamiliar—may have amygdalas that are *too easily* activated, causing the children to be aroused too readily by unfamiliar or stressful situations (Kujawa et al., 2016; Lahat et al., 2014).



World History Archive/Alamy Stock Photo

FIGURE 12.7 Bumps, lumps, and personality Franz Gall proposed that personality could be determined by measuring the bumps on a person's skull, and he diagrammed the areas associated with particular personality traits. While his assumptions were wrong, his idea that some brain functions are localized is true.

Cerebral hemisphere dominance may also contribute in subtle ways to personality. Some studies have hinted that people whose right hemisphere is dominant experience more negative emotions and traits while those whose left hemisphere is dominant display more positive emotions and traits (Reznik & Allen, 2018; Davidson, 1998). One study found, for example, that participants who were generally sad and withdrawn displayed less activity in the left side of their prefrontal cortex—the part of the brain responsible for planned actions and thought and, in part, for emotional reactions to stress (Pliszka, 2016; Davidson & Fox, 1989). Moreover, the link between hemisphere dominance and personality may appear at a very early age. Psychologists have studied the brains of infants who show high levels of distress when separated from their mothers. Results indicate that such infants and infants living is stressful, impoverished environments tend to display heightened activity in the right-side prefrontal cortex (DeSocio, 2018; Blair & Raver, 2016; Galea & Lindell, 2016).

Neurotransmitter activity has also been linked to some personality variables. As mentioned earlier in this book, the neurotransmitter dopamine helps regulate the "pleasure pathway" (Sayin, 2019; Ayano, 2016). It is central to the brain's reward systems. High dopamine activity in the reward centres, for example, has been associated with positive emotions, high energy, and lack of inhibition, while low activity of this neurotransmitter has been linked to anxiety, inhibition, and low energy levels (Cools, 2019; Zuckerman & Donohew, 2015). Similarly, low serotonin activity has been associated with depression, violent behaviour, and impulsivity (Coccaro et al., 2016; Manchia et al., 2017; Nautiyal & Hen, 2017; Knutson et al., 1998).

Hormonal activity, too, has been tied to personality. The important hormone cortisol, secreted by the adrenal cortex to help regulate reactions to threatening experiences, has been tied to personality. As you read in Chapter 4, for example, Jerome Kagan (2010) conducted a famous study of inhibited children in 1994. He measured the blood cortisol levels of children as they were reacting to stressful situations. Recall that cortisol helps

regulate reactions to threatening experiences. Kagan found that the children with inhibited temperaments tended to have higher cortisol stress reactions to unfamiliar situations. Recall that temperament (as discussed in Chapter 4) is a way to describe early-appearing stable tendencies toward particular emotional states (called reactivity) and the ability to manage these states.

Organizing Research Findings

Numerous studies have looked at the link between biological processes and personality, yielding findings that are complex and often confusing. One of the most compelling methods for organizing these findings has been suggested by the researchers Lee Anna Clark and David Watson, who grouped personality types into three broad categories of temperament, similar to the superfactors proposed by Eysenck and the Big Five theorists (Kotelnikova, Weaver, & Clark, 2019; Clark et al., 2017; Watson & Naragon-Gainey, 2014; Watson et al., 2015).

Negative emotionality Individuals who have high levels of negative emotionality are thought to experience more negative emotions and see the world as distressing, whereas those low on this dimension are relatively peaceful and have higher levels of satisfaction.

Positive emotionality Measures of positive emotionality are thought to represent a person's engagement with their environment. High scorers are social individuals who lead active lives and exhibit enthusiasm, while low scorers are shyer and have less energy and self-confidence.

Disinhibition versus constraint The disinhibition/constraint dimension reflects how we regulate our various emotions. People high in disinhibition have difficulty controlling their emotional responses and tend to be impulsive, living for the moment. People high in constraint live more careful and controlled lives.

Note that negative emotionality and positive emotionality are two separate dimensions. These two types of emotionality are not necessarily at opposite ends of a spectrum. A person may score high on both, low on both, or high on one and low on the other.

Scores on the three dimensions are broadly related to particular lifestyle patterns (see **Figure 12.8**). Individuals high in negative emotionality are more likely to experience feelings such as anger, contempt, and guilt, while those high in positive emotionality tend to experience positive emotions such as joy, excitement, and pride. Some problematic lifestyle patterns may be found among individuals who score high on the disinhibition dimension. These individuals, who are high in impulsivity and do not act with long-term consequences in mind, tend to get poorer grades in school, perform more poorly in their jobs, and engage in riskier activities, such as drinking and using illegal drugs (Lozano, Gordillo, & Pérez, 2014; Mullins-Sweatt et al., 2019). Interestingly, "morning people" are more likely to be high in positive emotionality, while many "night owls" are high on the disinhibition dimension (Kivelä, Papadopoulos, & Antypa, 2018; Clark & Watson, 1999).

Interpreting Research Findings

Although research findings suggest links between brain functioning and personality, we must, as always, take care in interpreting these findings. The links just discussed are not

usually straightforward, and personality traits are never the result of a single biological process. The activity of one neurotransmitter—say, serotonin—is, at most, *partially* responsible for the regulation of a trait or emotion. Clearly, the relationships between biology and personality that have been discovered represent only a small portion of the complex neurological system.

In addition, it is important to remember that the patterns of brain activity that we have observed have not been shown to provide a causal explanation of traits. Particular biological processes associated with personality may themselves be the results of environment and experience. As you have seen, for example, studies indicate that life experiences, even very early ones, may affect both biological make-up and personality patterns, present and future. One study of rhesus monkeys found that baby monkeys who had endured high levels of abuse and rejection by their mothers displayed lower levels of serotonin activity in adulthood. Moreover, the lower their level of serotonin activity in adulthood, the more likely they were to abuse their own offspring (Shah et al., 2018; Coyne & Maestripieri, 2016). Clearly, environmental factors, even at an early age, greatly affect the neurobiological system, and that impact can be enduring.

In summary, we must be very careful about the conclusions we draw from genetic and neurological personality research. First, we must keep in mind that the brain operates as a system, and personality reflects activity in a number of regions, as well as the expression of multiple genes (Bulbena-Cabre, Nia, & Perez-Rodriguez, 2018; Bouchard, 2004). Second, we must recall that one gene may interact with other genes and affect a variety of personality dimensions (Sanchez-Roige et al., 2018). Third, we need to recognize that the environment affects the operation and impact of both genetic and biological processes. Those processes in turn affect how individuals interact with their environment. Given the complex, bidirectional relationships that occur between traits, biological factors, the environment, and behaviour, the only certain conclusion that can be drawn is that much more research is needed before we can truly understand the nature and causes of personality (Maruszewski, Fajkowska, & Eysenck, 2010). Check out Your Brain and Behaviour 12.1 to find out what areas of our brains are involved in altruism.

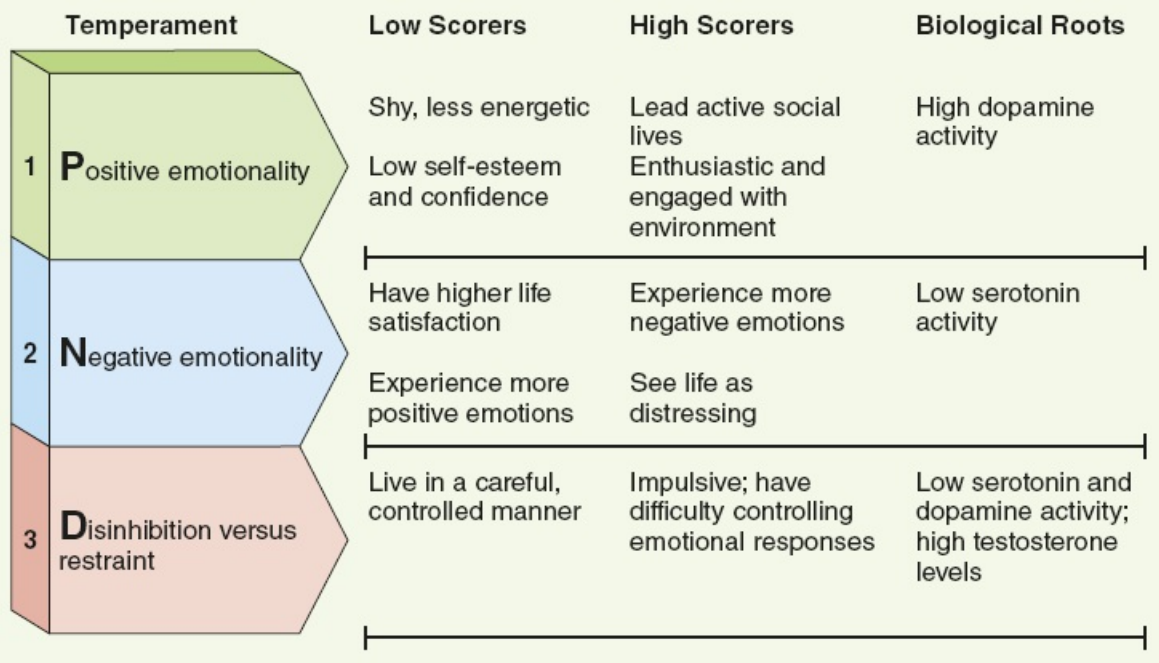


FIGURE 12.8 The biology of personality Clark and Watson grouped the findings from personality studies into three dimensions of temperament. Research evidence suggests that biological processes are at the root of these temperament dimensions.

12.1 Your Brain and Behaviour

Trait Theory, Altruism, and the Brain

Altruism is a core component of many cultures and acts of altruism are aimed at improving the welfare of another person; often it is defined selfless acts that help others with no expectation of reciprocity. Altruism is often thought of as specific to humans, however there are instances of altruism like behaviours in other species such as dolphins, primates, and elephants. In humans altruistic behaviours have been reported in young children and even infants (Filkowski, Cochran & Hass, 2016; Warneken & Tomasello, 2009).

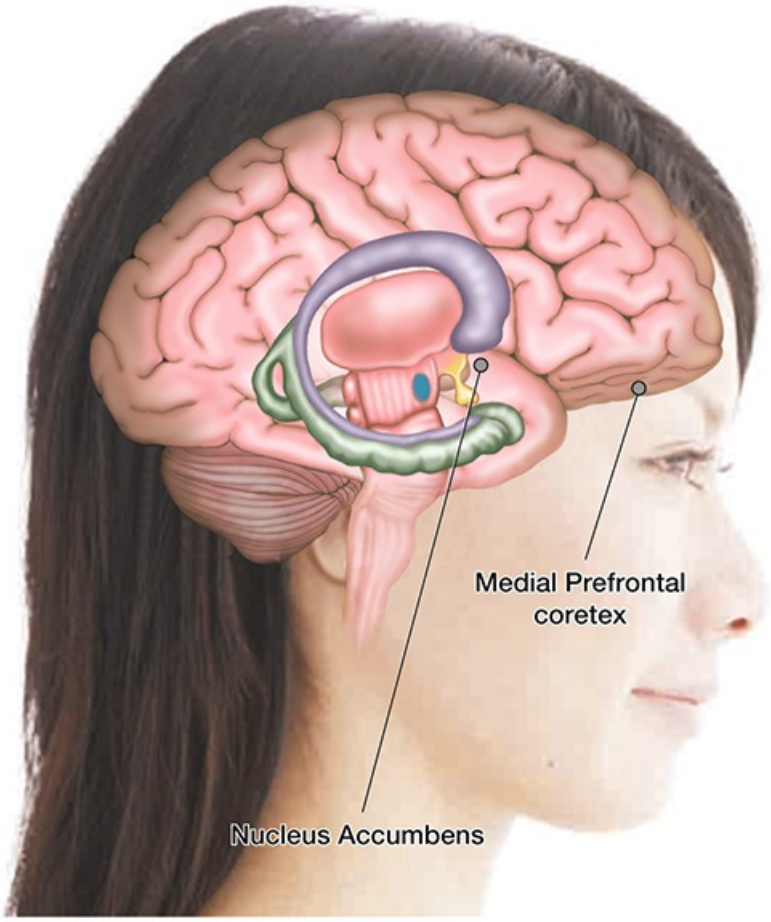
Specific personality traits (using the Big Five Personality Traits) may correlate to who we perform altruistic acts toward. A study from Britain also showed that people high on agreeableness, conscientiousness, and openness were more likely to value altruism and commit altruistic acts. (Furnham, Treglown, Hyde & Trickey, 2016). In work from Japan, researchers found that individuals high in conscientiousness were more likely to exhibit altruistic behaviour toward family members, those high in agreeableness were more likely to be altruistic with friends and acquaintances, and individuals higher in openness were more likely to help strangers (Oda et al., 2014). Whether this level of specificity between a personality trait of the giver, and the category of recipient receiving the assistance of the giver, stands the test of scientific scrutiny it does raise an interesting question - how is altruism activated in the brain?

Questions

What personality traits are more likely to exist in individuals who display altruism?

What areas of the brain are involved in altruism?

How does gratitude journaling affect the activation of the prefrontal cortex and nucleus accumbens during the imagination of an altruistic act?



Source: Digital Vision/Getty Images

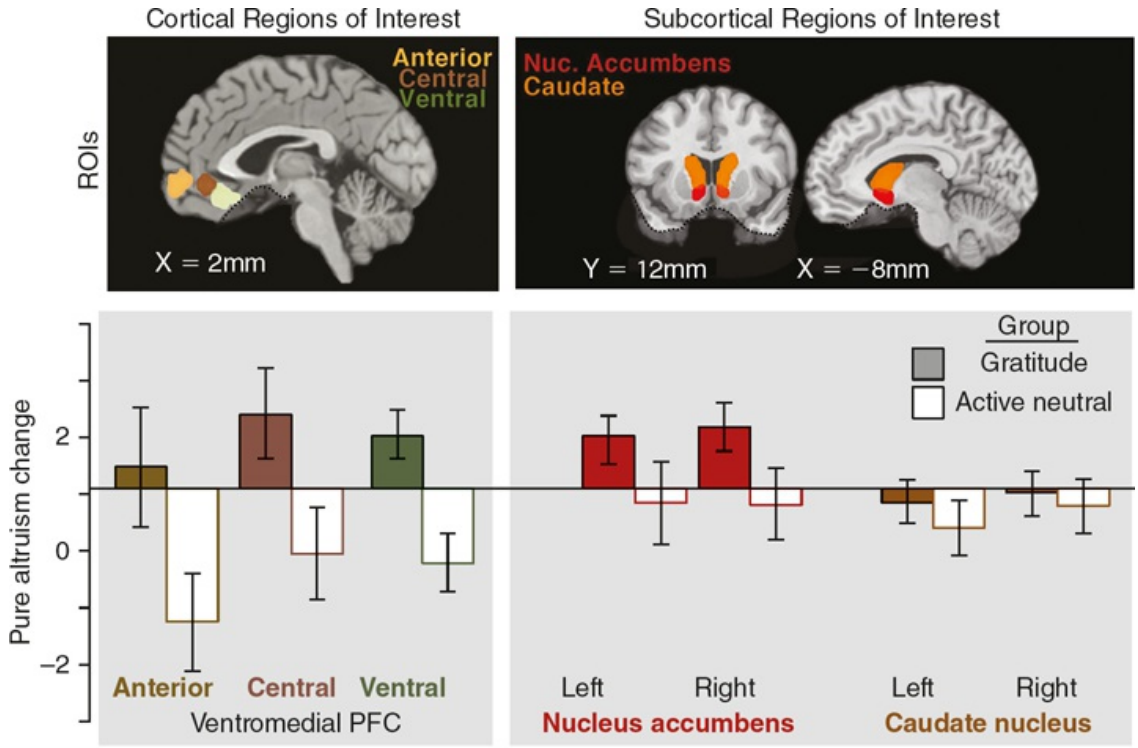
Selfless acts **Altruism can be as simple as bringing someone a warm cup of coffee or tea.**

Photo by Gabrielle Henderson on Unsplash

Altruism and the brain **Keeping a gratitude journal has been shown to increase activity in parts of the prefrontal cortex – specifically the ventromedial (in the middle and toward the bottom) portion of the PFC.**



Source: Filkowski, M. M., Cochran, R. N., & Haas, B. W. (2016). Altruistic behavior: Mapping responses in the brain. Neuroscience and Neuroeconomics, 5, 65.

Altruism and the prefrontal cortex **Recent neuroimaging work shows that there are several areas of the brain important for the expression of altruism including the prefrontal cortex and nucleus accumbens. How can you increase your likelihood of displaying altruism and changing your brain in that direction? In young women a double blind study was conducted where participants were assigned to either a gratitude journaling or control journaling condition for three weeks. During an altruism task the gratitude journaling group showed an increase in the neural activation of the prefrontal cortex and nucleus accumbens as compared to baseline. The caudate nucleus, an area involved in the control of movement, showed no change in activity levels (Karns, Moore III & Mayr, 2017).**

Before You Go On

What Do You Know?

18. What do we mean when we say that the Big Five dimension of openness has a heritability coefficient of .55?

19. What is thought to be the role of the amygdala in the development of inhibited personalities?

20. What are the three categories of temperament proposed by Clark and Watson?

21. Why is it necessary to be careful in interpreting research findings associating particular personality traits with particular biological substances or structures?

What Do You Think? • Many of the same brain structures are involved in both emotion and personality. Discuss what you think this suggests about the relationship between emotion and personality.

Differences in Personality

LEARNING OBJECTIVE 7

Explain how gender and cultural differences can affect personality.

So far we have focused on ideas about how personality unfolds. Let's turn now to the question of group differences in personality. Are male and female personalities inherently different? Do personalities differ among different cultures and subcultures? We will examine these questions next.

Michaeljung/Dreamstime/GetStock

Personality and gender differences **While some people argue that there are personality features that are more typical for one gender than the other, it is actually the case that there are more differences across individuals within each gender than there are across the genders.**

Gender Differences

The 1992 book *Men Are from Mars, Women Are from Venus* (Gray, 1992) has sold more than six million copies in North America and been translated into 40 languages. The book's premise that men and women are entirely different clearly struck a responsive chord. But how accurate is this notion?

Research into Gender Differences

A number of studies suggest that the widespread belief in inherent personality differences between men and women may be no more than a myth. Recent broad reviews of studies on gender differences in personality, cognitive abilities, and leadership have found that the similarities between men and women far outnumber the differences (Abdallah & Jibai, 2020; Schmitt et al., 2017; Hyde, 2014, 2016). Differences among individuals of each gender are much larger than differences between males and females (McCrae & Terracciano, 2017). (See photo.)

Beyond all this, gender researchers have begun to note the importance of context in investigations of psychological gender differences. The situational and social context of a study—for instance, the male-to-female ratio in the experimental room—can greatly influence the nature and size of observed gender differences (Goodale et al., 2018; Bussey & Bandura, 1999; Eagly & Wood, 2016). Many psychologists rightly stress that incorrect conclusions about certain gender differences can perpetuate stereotypes and improperly affect men and women at work, at home, and in their professional lives (Brannon, 2016).

Roger Ressmeyer/Corbis/Getty

A caring life Operating against the stereotype that females are consistently more nurturing than males, animal shelter worker Sam Wheeler has devoted much of his life to loving and caring for unfortunate dogs and cats.

Nevertheless, we must be clear that some consistent sex differences have been documented. For example, women, on average, tend to be more accurate than men at assessing emotion in other people (Thompson & Voyer, 2014; Lambrecht, Kreifelts, & Wildgruber, 2014). The psychologist Carol Gilligan—who, along with Karen Horney, was one of the first theorists to focus on how women differ psychologically from men—argues that women and men, in fact, are most comfortable with different perspectives on the

world, although she also emphasizes that one perspective is not superior to the other, and both men and women are capable of adopting the other's perspective—think of them as masculine and feminine orientations (Gilligan, 2011; Gilligan & Snider, 2018; Larrabee, 2016). Gilligan, who was introduced in Chapter 4, believes that women are more attuned to interpersonal (relational) concerns when making moral decisions, while men are more likely to base such decisions on laws or abstract principles. Building on this idea, she has found that men, on average, score higher on traits that reflect individuality and autonomy, while women score higher on ones that emphasize social connectedness and empathy (Gilligan, 1982). Similarly, some investigations have indicated that women tend to display more nurturing behaviours (Eagly & Wood, 2016). (See photo.)

After statistically comparing the results of many studies relating to gender differences in personality, psychologist Janet Hyde (2018, 2014, 2008) found only a handful of variables on which females and males differed consistently. Those that she did find, however, seem to be important. Levels of aggression—particularly physical aggression—were somewhat higher among males. In addition, males were quite different from females on measures of motor performance and sexuality, and males and females had strikingly different attitudes about sex in casual, uncommitted relationships—men were more open to sex in such instances. As we noted in Chapter 11, the data on gender differences in sexual attitudes may be influenced by research participants' awareness that society expects men and women to behave in certain ways sexually. Still, it is clear that, overall, differences in aggression and attitudes may lead to significant differences in the expression of personality.

Why Do Gender Differences in Personality Exist?

Knowing about gender differences is similar to looking at the results of a personality assessment—both provide descriptions but do little to explain *why* certain patterns exist and what those patterns may say about future behaviour. A number of theories attempt to explain the personality differences observed in men and women.

One theory explains these differences in socio-cultural terms. After all, a person's self-concept, life goals, and values all develop in a social context. According to **social role theory**, girls and boys develop different personal styles, behaviours, and skills based largely on the division of labour between the sexes and the resulting differences in gender role expectation*s* (Koenig & Eagly, 2014; Eagly & Wood, 2016; Koenig et al., 2011). In other words, males and females develop the personality attributes that are best suited for the roles that they typically occupy. Some theorists believe that play behaviour in childhood helps teach gender roles and expectations. Young boys are expected to play competitive games, for example, and often are given aggressive-type action figures as toys. Girls, in contrast, are encouraged to play games that emphasize nurturing and interacting with peers.

> **social role theory** theory that gender differences occur because girls and boys develop different behaviours and skills based largely on differences in gender role expectations.

begalphoto/Shutterstock.com

Social roles **Social roles, such as learning how to box with an aggressive attitude, are learned socially but become powerful influences on behaviour.**

Family and social relationships may also contribute to the development of personality differences between boys and girls. As children interact with their families and peers, they form ideas about gender role expectations based on how those other individuals react to their behaviours (see photo). It is particularly important that the reactions of others teach children what behaviours and ideas are not appropriate to their gender role (Henley, 1977). A little boy may, for example, face disapproval if he plays with dolls rather than action figures (Mayeza, 2018). Similarly, girls' home social environments influence whether they will consider studying and working in a STEM (science, technology, engineering, and math) discipline (Eccles, 2015).

Broad cultural practices, often a reflection of religious and philosophical beliefs, are also significant in the development of male–female differences. Traditionally, men held a position of higher power than women in most societies, and this power structure had a "trickle-down" effect on smaller units of behaviour. Women, for example, often were limited to certain roles, such as child rearing, domestic work, and particular occupations (nurse, teacher, secretary). It may be that women were more likely to develop certain personality traits as a result of these constraints. Consider, for example, the superior abilities of women, on average, to read emotions and to perform in the social realm. Individuals who are in positions of less power or privilege may need to develop their skills at recognizing interpersonal cues and spotting the emotions of those in power to better address their own needs (Eagly & Wood, 2016; Eagly & Koenig, 2006; Koenig et al., 2011). They can use such skills as they try to make sure their own needs are met.

A number of theorists further propose that cultural norms influence how men and women form their self-schemas. As we discussed in Chapter 4, *schemas* are ways we organize knowledge. A *self-schema* is an individual's cognitive framework for the knowledge he has about himself. When we need to process new information about ourselves or our interactions, we refer to these schemas for guidance. A number of studies suggest that men

are more likely to have self-schemas that emphasize autonomy and independence, while women are more likely to have collectivist or relationship-based schemas (Starr & Zurbriggen, 2017; Yarnell et al., 2015). One team of researchers further hypothesized that an individual's self-esteem would be directly related to how well he lived up to gender-dependent schemas—a hypothesis supported by a study they conducted (Hoyle et al., 2019; Josephs, Markus, & Tarafodi, 1992). Research participants who were led to believe that they equalled or surpassed most of their peers in gender-specific skills and abilities had consistently higher levels of self-esteem.

Efforts to break free from social roles can take a toll on individuals. Thus, even the best-intended role breakers can only go so far. Perhaps you have noticed, for example, that some men are willing to support a female friend by going to a female-oriented movie or a flower show, but the same guys are much less likely to hold a friend's purse. And on those occasions when men do go that extra mile, they are often left in an uncomfortable emotional state. Researchers Jennifer K. Bosson and Joseph A. Vandello (2011; Bosson, Vandello, & Caswell, 2014) asked men to engage in a braiding task—half of them braided a length of rope, and half of them braided hair. Afterward, the men were given the choice of punching a bag or working a puzzle. The men who braided hair overwhelmingly opted to punch a bag. In another condition, men who were not allowed to punch a bag or engage in other aggressive behaviours reported high anxiety levels. In essence, according to Bosson and Vandello, if the men didn't get an opportunity to reassert some gender-stereotyped behaviour, their sense of manliness became threatened.

In addition to such socio-cultural factors, biological factors may play a role in gender differences in personality. In Chapter 3, for example, we discussed the nature and importance of *hemispheric lateralization* in the brain. It turns out that males and females may exhibit different degrees of hemispheric lateralization. Male brains tend to be more functionally lateralized than female brains: in male brains, one hemisphere is relatively dominant for various kinds of processing, while female brains appear to be more integrated (Zhang et al., 2020; Grabowska, 2017). Still other studies have found that the sex hormones, testosterone and estrogen, which are available in different amounts and often act differently in males and females, have major influences on behaviour and personal tendencies, leading many theorists to believe that they also contribute to gender differences in personality (Schmitt et al., 2017; Nostro et al., 2016).

In summary, it is true that, on the one hand, many of our society's beliefs about male–female personality differences are incorrect or overstated. A number of psychologists worry that the Mars–Venus myth of massive gender differences serves to perpetuate harmful misconceptions. Highlighting differences between men and women, for example, may support prejudicial beliefs and discriminatory practices against women (Coates, 2018; Zell et al., 2016). On the other hand, it is also true that that there is potential danger in not acknowledging the real differences that do exist between the genders. Such denial, argue a number of theorists, may serve to downplay the unique strengths and gifts of each gender. Perhaps the most appropriate response to this debate was offered by psychologist Diane Halpern, past-president of the American Psychological Association. There may be limited differences between males and females, Halpern stated, but "differences are not deficiencies" (Halpern, 2012).

Differences Among Cultural Groups

Around the world, each culture is characterized by its own values, beliefs, and to some degree, patterns of behaviour. These features help guide members of the cultural group, teaching them what they should value in life, how they should treat others in their group, and how they should view themselves in relation to society. Cultures also form their own ideas about what is important in life, and these ideas can vary widely. For example, the term *self-esteem*, so important in North American culture, is not even found in a number of languages. Clearly, people who live in a society that does not emphasize self-esteem are less likely than North Americans to spend their lives striving for it. Similarly, in North America and Western Europe, a person's goals and life path are often influenced by the culture's emphasis on autonomy and accomplishment, whereas in Asian cultures there is greater emphasis on contributing to a community and honouring one's family (Abdel-Khalek, 2016).

Some of the most comprehensive cross-cultural research has focused on personality development in individualist and collectivist cultures. As we observed in Chapter 1, most collectivist cultures consider the needs of the group more important than the needs of the individual. With this orientation comes heightened emphasis on the role of individuals within their family and on social relationships in general. In turn, individuals are more likely to strive to help maintain the social order and to exhibit humility in social interactions (Stellar et al., 2018; Fiske, 2018). Collectivist values are particularly found in African, Latin American, Asian, and Middle Eastern cultures (Cohen, Wu, & Miller, 2016).

In contrast, individualist cultures value individual achievement, freedom, and success. The self is seen as independent, and each individual is thought to possess a set of psychological qualities that are distinct from those of others. Unlike collectivist cultures, individualist cultures consider individual attainment more important than the needs and values of others. Indeed, competition between individuals is valued. Countries known for this type of structure are Canada, Great Britain, the United States, and Australia.

Cross-cultural psychologists have uncovered some interesting personality variations between collectivist and individualist cultures (McCrae, 2017; Church, 2016; Galinha et al., 2016). One large, multi-nation study found that people in collectivist cultures tend to score higher on measures of agreeableness, for example, while people from individualist cultures score higher on measures of extroversion and openness (Allik et al., 2017).

Happiness and success may also be defined differently from culture to culture. In collectivist societies, contentment is related to harmony in interpersonal relationships, and this emphasis affects behaviour. Interpersonal behaviours are tailored to the feelings and needs of others (Mesquita, Boiger, & De Leersnyder, 2016; Hitokoto & Uchida, 2015). A strong sense of reciprocity and a responsibility to return favours shapes personal styles, behaviours, life goals, and measures of success. In such a culture, a sense of accomplishment comes not from individual achievements but from strong commitment to family, community, or company.

In contrast, people in more individualist cultures are less constrained by a tightly knit social network and enjoy greater personal freedom. They value their privacy and place a premium on individual human rights. Interestingly, some studies have found that people in individualist cultures report greater happiness than those in collectivist cultures (Igarashi,

2016; Heine, 2015). At the same time, however, individualist societies have higher rates of divorce, homicide, and stress-related disease than collectivist ones (Beltrán-Velasco et al., 2020; Yip et al., 2015; Hughes, Schaible, & Gibbs, 2015).

People's sense of their own personalities also differs across cultures. Individuals in collectivist cultures, for example, do not use traits to describe themselves as often as those in individualist cultures. Studies have shown that when students are asked to complete the phrase "I am . . .," those from North America are more likely to answer using a personal trait (say, "I am friendly" or "I am honest"), while those from cultures with a collectivist orientation are more likely to describe themselves in a social manner (for example, "I am a member of the psychology department") (McCrae, 2017). In light of such findings, some have argued that Western personality measures, such as the Big Five superfactors, are of limited usefulness in studying behaviour in collectivist cultures (McCrae, 2017; Church, 2016). (See photos.)

The interplay of culture and personality is also evident when people move from one environment to another. As people become entrenched in a new cultural context, they typically absorb the norms and values of the society. Indeed, research has revealed that when individuals move from a collectivist culture to an individualist one, their personal and behavioural patterns change. One study, for example, looked at the personality traits of Chinese students who were enrolled in universities in North America (McCrae et al., 1998; Allik & Realo, 2017). Those students who had been in North America the longest, and had presumably been more exposed to Western culture, showed higher levels of extroversion and had personality profiles more similar to those of other North Americans.

Interestingly, some people who come from bicultural backgrounds seem to develop the ability to "frame switch"—that is, to change back and forth between cultural frameworks as they interpret experiences. This suggests that they may have internalized the belief systems of both cultures (Mesquita, De Leersnyder, & Jasini, 2017). It is not yet clear what implications frame switching has for the ties between culture and personality. This is, however, an important question as the world moves each day toward greater cultural integration.

Jupiter Images/Getty Images

Tokyo Space Club/Corbis Images

Different values, different personalities The different ways in which these business meetings are being conducted in North America and Japan reflect the different values and personalities at work in individualist and collectivist cultures. Goals and personal styles in an individualist culture emphasize striving for autonomy,

individual achievement, and high self-esteem. In contrast, those on display in a collectivist culture emphasize the community, cooperation, and honouring one's family.

Culture, Socio-economic Environment, and Personality

A key aspect of culture is the socio-economic environment. Even in the most prosperous nations, there are distinct differences in living conditions between those in the lowest and those in the highest income brackets. These differences have actually increased across the world in recent years (Hanushek et al., 2020; Chmielewski, 2019). Although the relationship between socio-economic conditions and personality traits has received relatively little attention, investigations conducted to date suggest that it is an important topic (Ayoub et al., 2018; Flensborg-Madsen & Mortensen, 2014). At the very least, it appears that living conditions have a direct impact on how and whether certain personality traits translate into behaviours.

For example, Annie Yessine of the National Crime Prevention Centre in Ottawa and James Bonta of Public Safety and Emergency Preparedness Canada (2009) examined the trajectories of delinquent Indigenous youth in Manitoba. Data from the study indicated that chronically high offending youth were more likely to live in impoverished and unstable circumstances, to engage in substance use, and to experience negative peer interactions, suggesting that disorganized environments interact with individual characteristics to increase risk. Indeed, other studies directly assessed the impulsivity of a population of adolescent males. The teens in the studies came from a mixture of backgrounds, from wealthy households to poverty-stricken neighbourhoods. Their socio-economic status was found to clearly link with the outcomes of individual differences in impulsivity. Among boys who lived in poor neighbourhoods, those who displayed high levels of impulsivity were much more likely to engage in delinquent behaviours than those who displayed low levels of impulsivity. In contrast, among boys from high socio-economic status neighbourhoods, behavioural differences between those with low and high impulsivity were negligible (Ray et al., 2016; Lynam et al., 2000). To explain these findings, the investigators reasoned that poor neighbourhoods produce many more triggers for delinquent acts, whereas community structures in affluent neighbourhoods may offer limited opportunities for antisocial activities (see photo). In short, particular personality characteristics will result in particular behaviours only if certain situational triggers also are in place.

Syldavia/iStockphoto

Socio-economic class, impulsivity, and behaviour **Research suggests that impulsive boys from poor neighbourhoods may be more likely to engage in delinquent behaviours than impulsive boys from wealthier communities.**

Before You Go On

(Answers to Before You Go On may be found online in the Course Resources.)

What Do You Know?

22. What personality differences between men and women have researchers identified?

23. How does social role theory explain these differences?

24. What are some of the primary differences between the values of collectivist and individualist cultures, and how do these differences affect personality?

25. How does the socio-economic environment affect personality?

What Do You Think? • Think about the personality traits of a number of people you know. Include people of different genders and different cultural or subcultural groups. Do personalities seem to differ more on a group level or on an individual level among these acquaintances? How would you explain your observation?

Personality Disorders

LEARNING OBJECTIVE 8

Define personality disorders, and describe some of the key features of these disorders.

Imagine that a friend of yours is telling you about their brother Tom's relationship with his girlfriend, Sarah. Your friend explains that early in the relationship Sarah was exuberant and very attentive to Tom. After a while Tom started talking about how he was finding it stressful that Sarah texted him almost constantly at all hours when they were apart, asking him what he was doing and if he still cared for her. In addition, if he spent time with other friends Sarah would quiz him about what they did and act quite upset that he may have been having a good time without her. When Tom told her to relax, she would either get angrier or would apologize profusely and promise to never do it again. Recently Tom had decided to move on from the relationship and had been struggling with an incessant series of texts, emails, and tearful phone calls from Sarah that varied from venomous rants to pleas for reconciliation. Tom's summary of the situation was that "she is schitzy . . . she is crazy!"

What does this description of relationship behaviour suggest to us about Sarah? Was she the victim of emotionally distressing circumstances? Or was her destructive behaviour the result of dysfunctional personal characteristics? It appears that Sarah's initial positive feelings and excitement about someone new in her life were invariably followed by a turbulent phase of emotional outbursts and an eventual falling out. As you will see in Chapter 15 on psychological disorders, we tend to treat disorders such as schizophrenia categorically in the sense that someone who meets the diagnostic criteria is diagnosed as "having" the disorder. (This is likely not what is going on for Sarah, and therefore Tom's descriptor of her as "schitzy" is misplaced.) However, psychologists and people in general do not believe that personality works that way. In terms of personality, we do *not* say that someone *has* extroversion. Rather, we say that they score high on the extroversion scale. What about Sarah? Does she have an extreme personality profile? She is certainly out there on neuroticism! This pattern suggests that Sarah may have a **personality disorder**, an inflexible pattern of inner experience and outward behaviour that causes distress or difficulty with daily functioning. Such patterns are enduring and differ markedly from the experiences and behaviours usually expected of people (APA, 2013). As we suggested earlier in this chapter, each of us has a distinct personality and specific personality traits. Yet, for most of us, this distinct personality is also flexible. We are affected by situational factors, and we learn from our experiences. As we interact with our environment, we try out various responses to see which are more effective. This flexibility is missing in people who have a personality disorder.

> **personality disorder** an inflexible pattern of inner experience and outward behaviour that causes distress or difficulty with daily functioning.

The American Psychiatric Association, in working on the latest edition of the *Diagnostic and Statistical Manual* (DSM-5) (APA, 2013), debated whether to approach personality

disorders as involving extremes on personality dimensions or, as it had in previous editions, as diagnostic categories like other disorder categories such as depression or schizophrenia. Despite substantial support for the dimension approach, the APA editorial committee decided to stay with personality disorder categories for now but to add study of a dimensional approach to personality disorders to the DSM-5's section on research needed and encouraged (Cloninger & Svrakic, 2016; Bach & Sellbom, 2016). We will discuss personality disorders in more detail in Chapter 15. Let's have a look at a couple of examples of the current categorical approach and then we will take a brief look at the alternative dimensional approach that fits better with the trait approaches to personality we have discussed in this chapter.

Personality disorders usually become evident during adolescence or early adulthood, although some begin during childhood (APA, 2013). There is no specific data on the rate of personality disorders in Canada, though a large-scale study by Jennifer Hensel and colleagues at the University of Manitoba looking at the incidences of disorders among people with contact with the law and their victims showed rates similar to the American data (Hensel et al., 2020). International data suggest that the rate is somewhere between 9 and 13 percent of the general population (Volkert, Gablonski, & Rabung, 2018; Gawda & Czubak, 2017; Tyrer, Reed, & Crawford, 2015). As in Sarah's case, the effects of a personality disorder can sometimes be so subtle that they are initially unnoticeable. It may take multiple encounters over time for the maladaptive symptoms to become recognizable. In the latest edition of its diagnostic manual (DSM-5), the American Psychiatric Association (APA, 2013) states that all personality disorders share four core features:

rigid, extreme, and distorted thinking patterns (thoughts);

problematic emotional response patterns (feelings);

impulse control problems (behaviour); and

significant interpersonal problems (behaviour).

Clearly, these symptoms have a significant impact on the individual's functioning in school, at work, and in social and romantic relationships (Hepp et al., 2017; Berenson et al., 2011; Mason & Kreger, 2010).

Based on Tom's description, Sarah appears to be emotionally volatile, particularly when it comes to her relationships. Especially in the early stages of a relationship, she tends to see the men in her life as "perfect," but they inevitably fall from grace. Sarah also appears to have a high sensitivity to feeling abandoned, which leads to emotional outbursts. She may even cut herself or cause some other harm as a way of dealing with that negative emotion. Her outbursts and moodiness are off-putting to her boyfriends and most others in her life. All these features suggest that Sarah may be displaying **borderline personality disorder**. Borderline personality disorder is characterized by severe instability in mood and self-concept, which in turn contributes to a high level of instability in relationships (APA, 2013). Borderline personality disorder is often thought of as an emotion dysregulation disturbance (Sherry & Whilde, 2008; Berenbaum et al., 2003; Linehan & Dexter-Mazza, 2008) and will be discussed further in Chapter 15.

borderline personality disorder a personality disorder characterized by severe

instability in emotions and self-concept and high levels of volatility.

Leah Hennel/Calgary Herald, reprinted with permission of The Calgary Herald

Disregarding others **Ponzi-schemer and fraudster Milowe Brost, from Calgary, Alberta, was sentenced to 12 years in prison for defrauding thousands of investors of more than $300 million.**

Individuals who might be generally described as sociopaths are categorized within the DSM-5 with **antisocial personality disorder**. These individuals, most of whom are male, show an extreme and callous disregard for the feelings and rights of others. They typically exhibit impulsivity, egocentrism, and recklessness, along with a superficial charm. Dishonesty and deceit are at the root of their relationships. Indeed, they often form relationships with the intent of exploiting others for material gain or personal gratification (see photo). Many are irritable, aggressive, and quick to start fights, and a large number commit criminal acts (APA, 2013). A large study by Dan Offord (1933–2004) at McMaster University suggests that approximately 1.7 percent of the Canadian population shows signs of antisocial personality disorder at any one time (Offord et al., 1996). Another study by

Rodger Bland in the department of psychiatry at the University of Alberta suggests that the incidence of this disorder is about 3.7 percent (Bland, Orn, & Newman, 1988). Moreover, cross-cultural research has shown that similar antisocial patterns of symptoms are found in both Eastern and Western cultures (Zoccolillo et al., 1999).

> **antisocial personality disorder** a personality disorder characterized by extreme and callous disregard for the feelings and rights of others.

Many theorists have attempted to uncover the origins of personality disorders, and have highlighted factors such as the roles of biological predispositions, early experiences of abuse and neglect, and the pressures of poverty or otherwise harsh social environments (Morgan & Zimmerman, 2018; Newman et al., 2016; Arens et al., 2011). (See Psychology Around Us 12.1.) We will discuss borderline and antisocial personalty disorders and briefly discuss the other eight personality disorders that are defined categorically within the DSM-5 in Chapter 15.

There is broad interest in a dimensional approach to personality disorders (Hopwood et al., 2018; Herpertz et al., 2017). At its core, this approach is based on the idea that personality disorders involve stable behaviour patterns that reflect extreme ends of personality dimensions. One approach, taken by Delroy Paulus at the University of British Columbia and Paul Trapnell at the University of Winnipeg, involves examining what they call dark traits within personality. The initial dark triad included narcissism, Machiavellianism, and psychopathy (Paulhus, 2014; Furnham, Richards, & Paulhus, 2013; Paulhus & Williams, 2002) and was expanded into a dark tetrad by including sadism (Međedović & Petrović, 2015). These personality dimensions are described as subclinical, which means they describe behavioural tendencies among people in the general population that would not necessarily predict that people scoring at the extremes would necessarily meet the diagnostic criteria for a personality disorder in the categorical sense. If you dare, or are curious, you can find out how you score on a measure of the dark triad traits here: https://openpsychometrics.org/tests/SD3/. The dark traits approach has been shown to be predictive of self-identifying as an online troll, with sadism scores being the strongest contributor to the results (Duncan & March, 2019; Buckels et al., 2019; Buckels, Trapnell, and Paulus, 2014). The dark traits have also been shown to be associated with violent video game preferences (Greitemeyer, 2015) and tendencies to use Facebook to spy on others (Stiff, 2019; Craker & March, 2016).

12.1 Psychology Around Us

School Shootings and Videogames

On December 6, 1989, one of the deadliest shootings in Canadian history occurred at Montreal's École Polytechnique, when a young man killed 14 women students, injured 10 other women and four men, and then shot himself. The gunman claimed that feminists had ruined his life. Attempts to interpret motives for this and other shootings led researchers to focus on issues of violence against women (Fluehr-Lobban & Billson, 2013; Mancini Billson, 2005), as well as the role of previous child abuse and its relationship to violent behaviour (Young, Michael, & Smolinski, 2019; Denmark et al.,

2005), the role of bullying and victimization (Brown, 2018; Haner & Lee, 2017; Reid & Sullivan, 2009), the role of violence in the media, and the socio-political roles of poverty and isolation in society (O'Grady, Parnaby, & Schikschneit, 2010). The aftermath of the shootings at the École Polytechnique contributed to the passage of the Firearms Act in 1995, leading the way toward more stringent gun control laws in Canada (Rathjen & Charles, 1999). Investigators have also discovered that most school shootings are premeditated and carefully planned (Matt, 2017; Robertz, 2007).

For its part, the media has regularly tied school shootings, such as the American shootings at Columbine high school, to the playing of videogames—the two students who orchestrated the Columbine killings were, for example, avid players of Doom. But, it turns out that the behaviour of student-killers is not so easily explained. Three years after Columbine, the American Secret Service and the Department of Education published a joint report that looked at 37 school shootings over the past three decades. They concluded that only 12 percent of the school shooters had any interest in videogames (Vossekuil et al., 2002).

If videogames are not a major factor in most school shootings, what are the causes of these violent outbursts? Recent studies of the relationship between school shootings and videogames have found that family violence is more of a risk factor than fictional violence (Duplechain & Morris, 2014; Flannery, Modzeleski, & Kretschmar, 2013). Low self-esteem, depression, and antisocial personality patterns are also factors. In addition, as we observed earlier in this book, adolescent shooters are often the victims of bullying or rejection, and some fantasize for quite a while about revenge for perceived offences (Brown, 2018; Haner & Lee, 2017).

In light of these school shootings and other such incidents, reports (Leavitt, Spellings, & Gonzales, 2007; Cawood & Corcoran, 2019) recommend increased awareness of the warning signs of potential attacks, such as a student describing plans to hurt others on a website. The hope is that identifying and addressing problems early on may prevent students with mental health problems from reaching a point where there is no turning back.

More formally, the committee that was considering personality disorder related revisions to the Diagnostic and Statistical Manual spelled out what they called an alternative model of personality disorders (AMPD). A major concern with the categorical approach to personality disorders, noted above and discussed further in Chapter 15, was that many people who present with some sort of personality disorder end up in a catch-all diagnostic category called personality disorder—not otherwise specified. By taking a dimensional approach, the AMPD is intended to sort out this category and also shine some light on what contributes to the various personality disorder profiles (Waugh et al., 2017). **Table 12.4** shows the two main personality disorder criteria within the AMPD. Criterion A reflects the realization that all personality disorders share levels of general dysfunction at the level of the self (dysfunctions in identity and self-direction) and interpersonally (dysfunctions in empathy and intimacy). Criterion B reflects the dimensions of individual variation seen within personality disorders and consists of five trait domains, each of which is defined by a number of more specific facets or narrower traits. Besides using the term "traits," how are these personality disorder trait domains related to general personality? Well, they reflect

particularly extreme aspects of healthy personality traits described within the Big Five model, with negative affectivity reflecting extreme instability, detachment reflecting extreme Introversion, antagonism reflecting extreme disagreeableness, disinhibition reflecting extremely low conscientiousness, and psychoticism reflecting extreme openness to experience. There is a great deal of work being done to develop and validate scales for applying the AMPD. Candidate inventories to watch as work proceeds are the Personality Inventory for the DSM-5 (Krueger, Watson, & Widiger, 2020; Wright & Krueger, 2018; Krueger et al., 2012), the Personality Assessment Inventory (Busch, Morey, & Hopwood, 2017; Hopwood et al., 2013), and the General Personality Pathology Scale (Williams, Scalco, & Simms, 2018; Morey, 2017). These efforts to link personality disorders to a dimensional approach to personality will likely produce some very interesting results in the coming years.

TABLE 12.4

The Major Personality Disorders
Source: Based on American Psychiatric Association. (2013). *Diagnostic and statistical manual of mental disorders 5*. Washington, DC: APA.

Marked by Odd or Eccentric Behaviour
Paranoid: Exaggerated suspicion and distrust of others; assumption that others' motives are hostile; highly guarded and emotionally withdrawn
Schizoid: Detachment from social relationships; flat emotional expression; cold or indifferent to others
Schizotypal: Behaviour that is odd or peculiar; unusual cognitive or perceptual experiences; acute discomfort with close relationships
Involve Dramatic or Emotional Behaviour
Antisocial: Extreme disregard for others; relationships are dishonest, deceitful, and exploitive; typically impulsive and reckless
Borderline: Severe instability in emotion and self-concept; impulsive and self-destructive behaviour
Histrionic: Excessive need to be noticed and be the centre of attention; emotions shallow and changeable; engagement with others superficial
Narcissistic: Characterized by high degree of self-interest and self-importance; callous attitude toward others
Characterized by High Levels of Fear and Anxiety
Avoidant: Extreme feelings of inadequacy; avoidance of social activities; inhibited personal relationships; hypersensitive to criticism
Dependent: Excessive need to be cared for by others; clinging and submissive behaviour; difficulty making decisions
Obsessive-compulsive: Preoccupied with perfectionism and control at the expense of flexibility or enjoyment; excessive devotion to work and productivity

Before You Go On

(Answers to Before You Go On may be found online in the Course Resources.)

What Do You Know?

26. What is a personality disorder?

27. What do all personality disorders have in common?

28. What are some differences between the categorical and dimensional approaches to personalty disorders?

What Do You Think? • Personality disorders are popular subjects of fiction. Think about films or television programs that you have seen, and try to find examples of characters who may be displaying personality disorders.

Summary

The Psychodynamic Perspective

LEARNING OBJECTIVE 1 Summarize the main ideas of the psychodynamic view of personality development.

Personality refers to the unique characteristics that account for enduring patterns of inner experience and outward behaviour.

Sigmund Freud's psychoanalytic theory of personality depended to a large extent on his ideas about the conscious and unconscious mind. Most of the content of our minds, in Freud's view, is in the unconscious.

Freud proposed three central forces in personality development: the id, the ego, and the superego.

In Freud's view, personality develops as children pass through a series of psychosexual stages. Each stage is characterized by strong conflicts between the id, the ego, and the superego. Failure to resolve these conflicts can result in neuroses.

Conflicts result in anxiety, and Freud believed that we use unconscious tactics called defence mechanisms to protect ourselves from this anxiety.

Other psychodynamic theories include those of Alfred Adler, Carl G. Jung, and Karen Horney.

The Humanistic Perspective

LEARNING OBJECTIVE 2 Describe the humanistic theories of Abraham Maslow and Carl Rogers.

Humanistic theorists, including Abraham Maslow and Carl Rogers, emphasized people's basic goodness and their ability to fulfill their potential.

Maslow proposed that personality arises from people's striving to meet their needs. Human needs are arranged hierarchically, with self-actualization at the top level.

Rogers based his theory of personality on his ideas about the importance of self-concept. He believed that children need unconditional positive regard to develop healthy self-concepts.

The Trait Perspective

LEARNING OBJECTIVE 3 Summarize the leading trait theories, and describe how the five-factor theory has evolved from the work of Gordon Allport and Hans Eysenck.

Personality traits are tendencies to behave in certain ways that remain relatively constant across situations. Trait theorists such as Gordon Allport and Hans Eysenck first proposed that central traits affect a broad range of behaviour.

Allport conducted detailed case studies that sought to reveal the unique collection of traits at play for each individual.

Eysenck, using factor analysis, identified three personality superfactors: extroversion, neuroticism, and psychoticism.

Other trait theorists proposed the five-factor theory, which identified five major trait categories: agreeableness, extroversion, neuroticism, conscientiousness, and openness to experience.

Although traits play an important role in behaviour, they can be inconsistent over time and across different situations.

Personality Assessment

LEARNING OBJECTIVE 4 Describe the two major types of personality tests, and give examples of each.

Personality inventories are questionnaires that require individuals to respond to a series of true–false or agree–disagree statements designed to measure various aspects of personality.

Two widely used personality inventories are the *Minnesota Multiphasic Personality Inventory 2 (MMPI-2)* and the *Revised NEO Personality Inventory (Neuroticism, Extraversion, Agreeableness, Conscientiousness, and Openness to Experience*) (*NEO-PI-R*). The MMPI-2 is typically used to assess abnormal personality characteristics and inclinations. The NEO-PI-R evaluates traits associated with the five-factor theory of personality.

Projective tests are intended to tap into people's unconscious minds by having them interpret ambiguous stimuli. In the case of the Rorschach Inkblot Test, the stimuli are inkblots. In the case of the Thematic Apperception Test (TAT), they are black-and-white drawings.

The Situationist and Interactionist Perspectives

LEARNING OBJECTIVE 5 Describe and differentiate the situationist and interactionist

views of personality.

Situationism holds that behaviour is governed primarily by the variables in a given situation rather than by internal traits. The behaviourist B. F. Skinner could be said to have viewed personality from this perspective.

Interactionism focuses on interactions between persons and situations. Albert Bandura's social-cognitive theory is an example of interactionist theory. In Bandura's view, the environment, internal mental events, and behaviour all interact to affect behaviour through the process of reciprocal determinism.

Biological Foundations of Personality

LEARNING OBJECTIVE 6 Discuss the heritability of personality traits and some of the neural systems that may be involved in the expression of personality.

Twin studies, such as the Minnesota Study of Twins Reared Apart, suggest that many personality traits have strong genetic links.

Certain brain structures, neurotransmitters, and hormones have been associated with personality variables.

In interpreting links between genes, physiological factors, and personality, it is important to remember that the relationships are complex and multidirectional.

Differences in Personality

LEARNING OBJECTIVE 7 Explain how gender and cultural differences can affect personality.

Research has found many more similarities than differences between men's and women's personalities. Nevertheless, some consistent differences have been identified.

Socio-cultural factors are thought to play an important role in gender differences in personality. According to social role theory, for example, boys and girls develop different behaviours and skills based largely on the division of labour between the sexes and the resulting differences in gender role expectations.

Cross-cultural research into personality has focused on personality development in individualist and collectivist cultures. Some traits observed in these cultures reflect differing cultural values.

The relationship between socio-economic conditions and personality traits has received relatively little attention. However, the investigations that have been conducted suggest that at the very least, living conditions have a direct impact on how and whether certain personality traits translate into behaviours.

Personality Disorders

LEARNING OBJECTIVE 8 Define personality disorders, and describe some of the key features of these disorders.

A personality disorder is an inflexible pattern of inner experience and outward behaviour that causes distress or difficulty with daily functioning.

The American Psychiatric Association uses a categorical approach to personality disorders such as borderline and antisocial personalty disorders but is investigating a dimensional approach.

Self-Study Questions

Multiple Choice

1. In Freud's view, personality forms as the result of the struggle between

a. biological drives and intellectual abilities.

b. conscious and unconscious processes.

c. primal needs and social or moral restraints.

d. the individual and other people.

2. Maslow believed that we can learn the most about the human condition by

a. creating an atmosphere of openness, honesty, and freedom from judgment.

b. paying attention to the unconscious symbols in our collective ancestry.

c. studying normal people.

d. studying those with psychological problems.

3. A person who follows rules, is dependable, and checks her work carefully is probably high in which of the Big Five personality traits?

a. Agreeableness

b. Conscientiousness

c. Extroversion

d. Openness

4. All of the following statements about personality traits are true except

a. Between three and five of the Big Five personality traits can be found across all cultures.

b. Traits are not always stable across situations.

c. Traits are powerful and difficult to disguise.

d. Traits are stable and consistent over time and across situations.

5. According to Skinner, what we call personality is simply consistency of what tendencies?

a. Environmental

b. Latent

c. Response

d. Situational

6. The Minnesota Study of Twins Reared Apart found that

a. both family environment and genetics predicted psychological similarity equally well.

b. family environment was more important than genetics in predicting psychological similarity.

c. genetics was more important than family environment in predicting psychological similarity.

d. the interaction between genes and environment prevented the researchers from drawing firm conclusions.

7. According to research, people who score high on Clark and Watson's disinhibition dimension are more likely to

a. be morning people.

b. feel anger, contempt, and guilt.

c. lead active lives and exhibit enthusiasm.

d. perform more poorly at work and engage in risky activities.

8. In collectivist cultures, happiness and a sense of accomplishment tend to come from

a. harmony in interpersonal relationships.

b. one's achievements at work.

c. personal freedom and privacy.

d. the amount of money one makes.

9. Personality disorder is best defined as being

a. an inflexible pattern of inner experience and outward behaviour that causes distress or difficulty with daily functioning.

b. characterized by a high degree of self-interest and a high, often unrealistic, degree of self-importance.

c. characterized by extreme and callous disregard for the feelings and rights of others.

d. characterized by severe instability in emotions and self-concept and high levels of volatility.

10. All of the following are characteristics of projective tests except that they

a. have a validity scale built into them that guards against socially desirable responding.

b. have problems with reliability.

c. include the Rorschach and the TAT.

d. rely on clinicians' judgment for analysis.

Fill-in-the-Blank

1. According to Freud, the _____ operates on the reality principle and the _____ operates on the pleasure principle.

2. In Freud's theory, the _____ stage of psychosexual development includes identification with the same-sex parent.

3. Rogers claimed that in order to develop a positive self-concept, we need to accept ourselves and to receive _____ from important people in our lives.

4. A person who frequently experiences negative emotions is probably high on Eysenck's superfactor of _____.

5. The finding that different people respond to the same reinforcer in different ways is a problem for the _____ view of personality, leading most researchers to prefer an interactionist approach.

6. Although research proved it to be incorrect, Gall's theory of _____ was important to our later understanding that particular brain areas have particular functions.

7. Some psychologists believe that inhibited children may have an overactive _____, a part of the brain important to the experience of negative emotion.

8. According to _____ theory, the gender differences typically seen in skills and behaviour are largely due to the division of labour between men and women.

9. A person who is charming and manipulative and who does not feel guilty when he hurts others' feelings or takes advantage of them is likely to have _____ personality disorder.

10. Test items that are built into a personality assessment to control for social desirability responding are referred to as _____ items.

CHAPTER 13
Social Psychology

ERIC THOMAS/Getty Images

CHAPTER OUTLINE

Social Cognition: Attitudes

LEARNING OBJECTIVE 1 Explain how attitudes form and change and what role they play in behaviour.

Social Cognition: Attributions

LEARNING OBJECTIVE 2 Discuss how people make attributions to explain their own behaviour and the behaviour of others.

Social Forces

LEARNING OBJECTIVE 3 Describe the power of conformity and obedience in shaping people's behaviour.

Social Relations

LEARNING OBJECTIVE 4 Review major concepts in the areas of group dynamics, helping behaviour, aggression, and interpersonal attraction.

Social Functioning

LEARNING OBJECTIVE 5 Describe the major findings of social neuroscience about regions of the brain particularly important to our social functioning.

To say 2020 was an interesting year would be a hysterical understatement. It is no small undertaking to reflect on your own experiences with the massive social psychology experiment defined by the global coronavirus pandemic and the outpouring of concern over issues of racism, racial justice, and policing that were raised by several incidents, such as the deaths during police incidents of George Floyd in Minneapolis and of Indigenous

Canadian woman Chantel Moore in Edmundston, New Brunswick. In fact, the situation was not an experiment of any sort as it involved the entire population and was radically changing our lives.

In relation to COVID-19, think back to May 2020 and to the challenges of social isolation, social distancing, mask wearing, working or studying or simply being unemployed from home, communicating, socializing, and, perhaps, socially drinking via Zoom. We were all trying to come to terms with the wide array of social, economic, health, and personal uncertainties about the immediate, near-, and far-term futures. Hopefully, things are better for you now as you read this than they were then, though being only able to hope for that to be true was and likely still is a part of our uncertainties. Many of the direct stresses and anxieties associated with the pandemic will fit clearly into the types, categories, and responses to stress that will be discussed in Chapter 14. However, there are many aspects of our pandemic experiences that were linked to indirect, harder-to-see or to understand stressors. For example, social distancing—having to keep at least two metres away from someone—is simple to understand but how we spatially manage ourselves when we are out in the world is based on sociocultural norms that we learned and automated years ago when we were young. We knew we had to keep away from others, but doing so felt weird.

In the same vein, Zoom and other videoconferencing platforms made it easy for us to meet in virtual "face-to-face" fashion, but there are may ways in which a video session is not the same as face-to-face interaction. Eye contact, an important part of communication, is difficult because to have it appear to happen, you have to look into your camera instead of into the image of the face of the person you are talking to. A lot of the body language we use quite automatically to let us know whose turn it is to talk or who should respond to something someone else says is either unclear or entirely unavailable in a video call. As well, all sound in a video call shares the same data channel and so all directional cues are lost. Further, if two people happen to speak at once, the limited sound channel typically selects whichever speech stream was started first, making it hard to even hear, let alone sort out what the other person is saying. None of these things matter very much in a formal business meeting, where who is supposed to be speaking when and about what is usually laid out in advance in an agenda. In social video calls, however, they can add significantly to the information processing and social interpretation demands of the experience. Videoconference fatigue (see photo) is real and arises from the ways that these sessions limit or eliminate our access to many sources of social information we learned about and came to automatically monitor and react to years ago. Having to do without them or to find ways to replace the lost social information is stressful in ways that we are not fully aware. So, as if all the directly stressful aspects of the COVID-19 pandemic were not more than enough, we are also carrying the impacts of a broad array of indirect stressors, meaning that our overall social and personal stress levels are actually significantly higher than we are acknowledging.

What about having to wear masks (see photo)? Health science aside, our old social norms about masks usually involved self-protection, perhaps from germs or from being identified while we are trick-or-treating or robbing a bank. With COVID-19, health science suggested that we should wear masks in order to protect other people from our spit and breathing or coughing vapours. The incompatibility of these two sets of social norms, old and new, created some resistance to wearing masks—more so in the United States. Hopefully by the

time you read this, these conflicts have been sorted out on both sides of the border, but as we write this, it is yet another thing adding to stress.

Matthew Horwood/Getty Images

Pandemic related shifts in social norms Left, before the COVID-19 pandemic few knew about or used Zoom. Now Zoom fatigue is common. Right, tensions tied to old social norms regarding mask wearing sometimes boiled over.

Social psychologists study, among other things, the broad array of sources that we draw upon for information as we engage in social interaction. They can help us to see more clearly the direct and not so direct social changes and social norm shifts that escalated our uncertainty and stress levels through 2020.

In the midst of the COVID-19 outbreak, the issues of racism and police violence were broadly taken up both in terms of the #BlackLivesMatter movement following the death of George Floyd at the hands of police in Minneapolis and similar issues among Indigenous peoples following the death of Chantel Moore on June 24 in Edmundston, New Brunswick. At issue are matters of overt racism and, most importantly, matters of structural or implicit racism that have supported racially linked imbalances favouring Whites or settlers over people of colour or of Indigenous heritage in terms of access to resources, education, jobs, and basic safety. The over-representation of Blacks in American prisons (Bronson & Carson, 2019) and Indigenous people in Canadian prisons (Campbell & Wellman, 2020), the over-representation of both groups in the lower socio-economic class (Hajizadeh et. al, 2018; Quillian, 2017), and their significant over-representation among those who died during interactions with the police are key markers of systemic racial issues. In Canada, over the past 20 years, Indigenous people have accounted for 16 percent of those killed by the police while making up only 4.2 percent of the population, while Blacks accounted for 8.6 percent of such deaths while making up 2.9 percent of the population (Council of Canadian Academies, 2019). In the first half of 2020, the number of individuals killed in encounters with police was at 30, which is the average *annual* total across the previous 10 years (Flanagan, 2020). Calls to defund the police are not aimed at punishing police but rather at recognizing that the word “order” in the typical police mandate of law and order is premised upon a definition of order that is skewed along racial lines and that parts of police funding would be more effectively directed toward better means of addressing mental health and other needs than by police deployment. As well, calls for justice for missing and murdered Indigenous Canadian women.

What do you make of the concept of systemic racism? Is it different than a lot of individuals holding personal racist attitudes and if so, how is it different and how might we, or *must* we, address it? Social psychology may provide some useful insights here too. Social psychologists devote themselves to the study of human interconnectedness. Unlike many areas of psychology that focus on individual difference, such as personality or atypical development, social psychology is based on the belief that "it is not so much the kind of person a man is, as the kind of situation in which he finds himself that determines how he will act" (Milgram, 2004, p. 101).

We might think of social psychology in a general way as the scientific study of how people are affected by other people. This informal definition covers considerable territory. Many aspects of an individual's functioning may be affected by others—thoughts, feelings, and behaviours may each reflect the influence of the social environment. Moreover, the influence of others may be direct or indirect.

Given the many ways in which people affect one another, the pioneering psychologist Gordon Allport (1954) offered a more detailed definition of social psychology that is embraced by most people in the field. That is, **social psychology** seeks to understand, explain, and predict how our thoughts, feelings, and behaviour influence and are influenced by the actual, imagined, or implied presence of others (Allport, 1985).

> **social psychology** an area of psychology that seeks to understand, explain, and predict how people's thoughts, feelings, and behaviours are influenced by the actual, imagined, or implied presence of others.

Which pieces of this definition should social psychologists focus on? Many social psychologists have concerned themselves with **social cognition**—how people perceive and interpret themselves and others in their social world. They have examined, for example, the attitudes people hold and the attributions that people make. Other social psychologists have paid more attention to social forces and social interactions. We will discuss each of these areas on the following pages, and examine what happens in the brain during social functioning.

> **social cognition** the way in which people perceive and interpret themselves and others in their social world.

Social Cognition: Attitudes

LEARNING OBJECTIVE 1

Explain how attitudes form and change and what role they play in behaviour.

There are few things in our world that we do not evaluate in some form or another. On some evaluations, people tend to agree. For example, most people believe that natural disasters (wildfires) are bad, that horror movies are scary, and that babies deserve love. On other topics, people are more divided—such as the proper role of government in people's

lives, the best ice cream flavour, and the advisability of legalizing drugs. Psychologists refer to our relatively stable and enduring (within individuals) evaluations of things and people as **attitudes** (Morin et al., 2015; Smith & Ratliff, 2015; Howell, 2014; Noels, Kil, & Fang, 2014).

attitudes relatively stable and enduring evaluations of things and people.

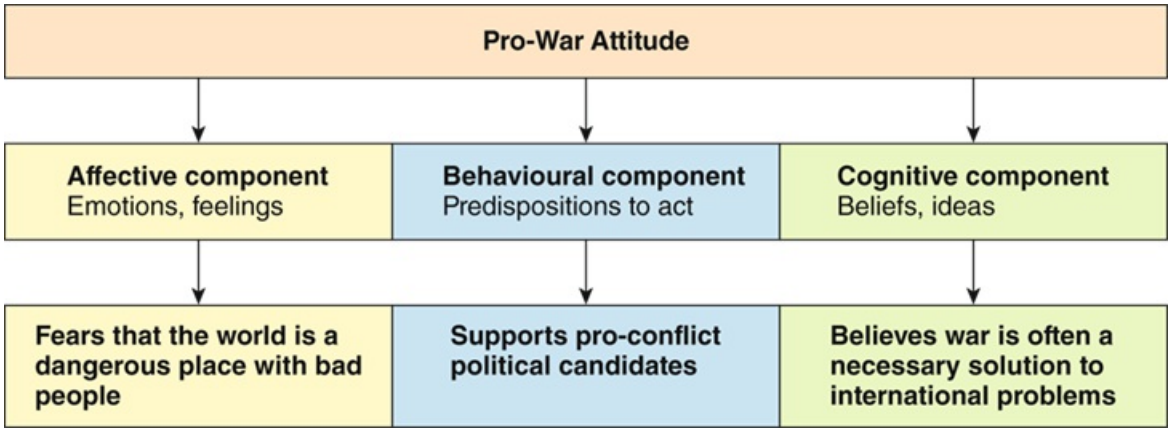

FIGURE 13.1 The ABC model of attitudes

According to the **ABC model of attitudes**, attitudes have three components, as shown in **Figure 13.1** (Jain, 2014):

The *affective* component—how we feel toward an object.

The *behavioural* component—how we behave toward an object.

The *cognitive* component—what we believe about an object.

ABC model of attitudes a model proposing that attitudes have three components: the affective component, the behavioural component, and the cognitive component.

Before the attacks on New York and Washington on September 11, 2001 when two planes were flown by terrorists into the World Trade Center north and south towers in New York city and one was flown in to the Pentagon, many North Americans held the attitude that their everyday world was safe from terrorism. They felt secure (affective component), went to work each day confident that terrorism would not touch their lives (behavioural component), and believed they were safe (cognitive component) (Ciuk, 2016; Steele, Parker, & Lickel, 2015). While many believe that the American response was generally disproportionate to the actual level of threat (Mueller & Stewart, 2012), general surveys of Canadians indicate that most feel generally safe with 94 percent reporting satisfaction with their safety in 2004, 93 percent in 2009 (Statistics Canada 2009) and 88 percent in 2014 (Perreault, 2017). Nevertheless, attitudes based on a fear of "other" (a phobia known as xenophobia) is a factor in hate crimes worldwide (Perry, 2016). Canada is also affected; hate crimes contribute to the number of violent crimes committed in Canada each year. The General Social Survey on Victimization (Allen & Boyce, 2013) indicated that 5 percent of reported incidents (almost 399,000 incidents) were deemed to have been motivated by

hate (65 percent due to race, 30 percent due to age, 22 percent due to religion, and 11 percent due to sexual orientation). Perhaps 5 percent seems a negligible number, but to the almost 400,000 people affected by hate-fuelled violence yearly, the numbers are frightening. But attitudes can change. We will explain the mechanisms by which attitudes change later in this section, but first, let's discuss how attitudes form in the first place.

Attitudes

Early in life, parents play a major role in shaping children's beliefs and opinions about things and people (Hill, Burrow, & Sumner, 2016; Simpkins, Fredricks, & Eccles, 2012). As we observed in Chapter 4, children are socialized when they acquire beliefs and behaviours considered desirable or appropriate by the family to which they belong. You are reading this textbook right now because you have been socialized in a number of ways—perhaps to believe in the value of a post-secondary education or the need for hard work to achieve your goals. This socialization may have occurred by direct transmission (your parents lecturing you about these values) or in subtler ways (Grusec & Hastings, 2014). Perhaps your mother or father praised you for your grades or punished you for not doing your homework. Over time, you might generalize these individual experiences into an overall attitude about the value of what you are doing.

Jose Luis Peleaz/Blend Images/Corbis

Shaping attitudes **Many school-age children today support recycling. What influences in the media and the general culture may have helped to shape this child's attitude?**

As children mature, their peers, their teachers, and the media also begin to significantly influence their attitudes (Bukowski et al., 2015; Prislin & Crano, 2012. (See photo.) Recall that in vicarious learning, children observe their classmates and take note of the rewards and punishments those students experience based on their behaviour. If a child sees a classmate rejected by the rest of the class for making disparaging remarks about a particular ethnic group, for example, the child may develop an attitude that such remarks are inappropriate and unacceptable. Similarly, seeing a favourite television character get whatever he wants by bullying people might foster an attitude that aggression is an acceptable way to achieve one's goals. Thus children learn attitudes in similar ways to the way they learn about other aspects of the world (Verkuyten & Thijs, 2013). Social Media also plays a role in how children (and everyone else) connect with their peers and social groups where FOMO plays a central role. What is FOMO? Well you can find out in Positive Psychology 13.1.

How Do Attitudes Change?

In addition to outside influences, we are also, of course, instrumental in shaping our own attitudes; that is, in addition to outside influence, the self is also a key source of attitude change. Such self-generated thought can have an important impact on our attitudes (Petty & Briñol, 2015). Research shows that just thinking about something makes it more significant and important to a person and explains, at least in part, why attitudes tend to become more extreme over time even when there is no additional exposure to outside information. Proponents of this phenomenon have dubbed it the *mere thought effect* (Tesser, 1978). They suggest that when people have more time to think about something, they generate more attitude-consistent thoughts and these thoughts serve to polarize (i.e., make more extreme) the attitude associated with them. However, Clarkson and associates (2011) argue that polarization of an existing thought is not due simply to additional thought; instead, they argue that people become more confident in their attitudes and thoughts as they marshal more attitude-consistent thought. Can such self-generated attitudes be changed?

13.1 Psychology Around Us | Positive Psychology

Combatting FOMO (Fear of Missing Out)

We've all experienced some level of FOMO anxiety (fear of missing out), whether it be feeling like we missed out on something when checking a Snapchat streak, Instagram, TikTok, or text messages. The phenomenon that encompasses FOMO is not new. Indeed, the human need to belong is a fundamental drive that is likely tied to how our ancestors survived in the distant past. With our current technology, however, it's been magnified in ways we couldn't have predicted even 15 years ago.

Increasingly, social media is becoming the defining way for people to feel connected to their friends, as opposed to getting together in-person—especially during the

lockdowns due to COVID-19. People with lower self-esteem are more likely to seek peer approval through social media and experience a greater degree of FOMO (Dogan, 2019). Researchers have found that increased social media activity does not provide a sense of enhanced social connection; rather, those who used social media more often were more likely to report a decreased sense of social connection (Roberts & David, 2020). Further, other studies have shown that adolescents with more social media engagement were more likely to report symptoms of inattention, ADD, anxiety, and depressive symptoms than those with more limited social media access (Barry et al., 2017).

There is some good news, however, for decreasing the anxiety and loneliness that can go along with social media and FOMO. One study of university students (Hunt, Marx, Lipson, & Young, 2018) found that limiting the use of three top social media platforms to 10 minutes per day (each) resulted in significant reductions in loneliness and depression over the three-week course of the study. Anxiety was also reduced over the baseline, as was FOMO, which led researchers to conclude that self-monitoring behaviour that limits time spent on these platforms can be beneficial to reducing anxiety and FOMO. In Chapter 9 we introduced the concept of metacognitions. Recent work suggests that creating positive metacognitions about social media may decrease FOMO and help decrease problematic social media use and its effects on our sense of self-esteem and self-worth (Casale, Rugai, & Fioravanti, 2018). While social media is here to stay, it's important to be aware of its effects on FOMO and to try to maintain our positive metacognitions and in-person connections.

Pixabay

Social media is here to stay However, maintaining our in-person social connections is an important way to avoid FOMO.

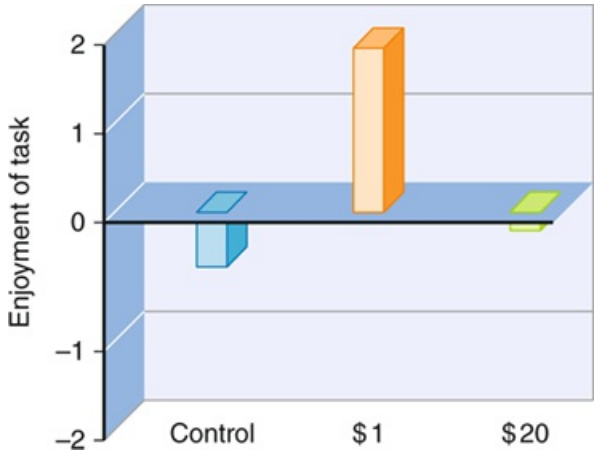

FIGURE 13.2 Cognitive dissonance After describing a boring task as fun, participants in Festinger and Carlsmith's study were asked to rate their own enjoyment of the task on a scale of 25 to 15. Those paid $1 ($8.50 today) for praising the task rated the task as more enjoyable than those paid $20 ($170 today) for praising it.

Source: Adapted with permission of John Wiley & Sons, Inc., from Kowalski, R., & Westen, D. (2009). *Psychology* (5th ed.). Hoboken, NJ: Wiley, p. 614; based on Festinger, L., & Carlsmith, J. M. (1959). Cognitive consequences of forced compliance. *Journal of Abnormal and Social Psychology, 58*, 203–210.

Once we have internalized a particular attitude—that is, once we have made it our own—how rigid and long lasting is that attitude? Can people experience a change of heart? In a classic social psychology experiment in the late 1950s, researchers Leon Festinger and J. Merrill Carlsmith (1959) demonstrated that when we are subtly manipulated into doing or saying something that is contrary to our private attitudes, we often change our attitudes to match the new action or statement.

In their study, Festinger and Carlsmith had research participants engage in a number of repetitive and boring tasks, such as spending an hour slowly turning square pegs on a board or adding spools to a tray and then removing them. After the tasks were done, the experimenters told the participants that the experiment was over and that they would be allowed to go home shortly—but in truth the experiment had just begun! Each participant was next told that a new group of individuals would soon arrive—individuals who would be performing the same tedious tasks but would be told ahead of time that the tasks were actually "fun" and "intriguing." The experimenter further asked each participant to help out by describing the upcoming tasks as fun and exciting to one of the new individuals. (All of the new individuals were in fact *confederates*. Confederates are people who are collaborators with the experimenters and are acting a part. In experiments where confederates play a role, participants believe the confederate to be the actual person they are pretending to be.) In spite of having found the task to have been really boring in almost all cases, the participants agreed to tell the new individuals that participating in the task was an enjoyable experience. Prior to meeting with the waiting "student" (recall this was actually a confederate), some of the participants were told they would be paid $1 (or about $8.50 today—a small amount of money) for helping out in this way, while others were told

they would receive $20 (about $170 in today's dollars).

After presenting the positive spin on the tedious tasks to the new individuals, the participants were then asked by yet another confederate presented as conducting a research experience survey for the psychology department to evaluate the experiment and to say how enjoyable they themselves actually believed the tasks to be. This was, in fact, Festinger and Carlsmith's (1959) central area of interest. Many of the participants paid $1 for "talking up" the tasks reported the tasks to be most enjoyable, whereas those who had been paid $20 were much less likely to report the task as enjoyable (see **Figure 13.2**).

How could participants come to find the mind-numbing tasks of this study enjoyable? Why did those paid less money to convince someone else that the tasks were enjoyable find the tasks *more* enjoyable than those paid more money to do so? Theorists have offered two possible answers to these questions.

Cognitive Dissonance Theory

Festinger (1957) proposed that when we hold two contradictory beliefs, or when we hold a belief that contradicts our behaviour, we experience a state of *emotional discomfort*, or **cognitive dissonance**. This state is so unpleasant that we are motivated to reduce or eliminate it. One way of removing dissonance is to modify our existing beliefs (Gawronski, 2012). In Festinger and Carlsmith's (1959) study, cognitive dissonance theory would hold that the conflict between the participants' initial attitudes about the tasks (that the tasks were boring and trivial) and their later behaviour (telling someone that the tasks were enjoyable) resulted in cognitive dissonance, and this unpleasant state motivated them to change their attitudes about the tasks in positive directions (that is, to believe they actually did enjoy the task, or at least that they found it less unpleasant).

> **cognitive dissonance** a state of emotional discomfort people experience when they hold two contradictory beliefs or hold a belief that contradicts their behaviour.

But what about the differing results for the participants in the $1 condition and those in the $20 condition? According to dissonance theory, the participants in the $20 condition experienced less dissonance because they had sufficient justification for their behaviour. Since they were well paid to say that the tasks were enjoyable, they could tell themselves, "I said the experiment was fun because I got quite a lot of money for saying it." (Remember that $20 was worth over eight times more in the late 1950s than what it is worth today.) Thus, these participants experienced little or no discrepancy between their attitudes and their behaviour. In contrast, those who received only $1 for their positive statements had insufficient justification for their behaviour and so experienced a marked discrepancy and uncomfortable feelings of dissonance. These participants managed to reduce the uncomfortable feelings by modifying their beliefs about the tasks—that is, by later reporting (and indeed, believing) "the tasks really were kind of interesting."

Anthony-Masterson Photolibrary/Getty Images

Serious dissonance **The contradiction between this doctor's professional commitment to health and his smoking behaviour may produce noxious feelings of dissonance. To reduce these feelings, he may adopt a belief such as, "Smoking helps me relieve stress and too much stress is a serious health risk."**

Festinger's theory of cognitive dissonance has received support from hundreds of studies (Chaxel & Russo, 2015; McGregor, 2013; Wicklund & Brehm, 2013) that support Festinger's contention that dissonance creates both psychological and physiological discomfort. For example, Omid Fotuhi and colleagues from the University of Waterloo (2013) telephoned smokers from four countries (Canada, United States, United Kingdom, and Australia) over three successive time periods to ask them about their smoking-related beliefs as well as to inquire about quitting behaviour. The researchers report that smokers who were not trying to quit smoking in any of the time periods as well as those who had tried to quit but relapsed had the highest levels of rationalization for their smoking behaviours. Cognitive theory would support this finding; this theory predicts that we would ignore information that contradicts our beliefs. Kneer and colleagues (2012) argue that most smokers simply refuse to consider the health aspects of smoking (Jiraniramai et al., 2015). (See photo.) Shawn O'Connor and associates at the Ontario Tobacco Research Unit have shown that similar challenges exist in efforts to get teens to attend to the health issues involved in vaping, yet another dissonance issue (O'Connor et al., 2019).

Somewhat recent work involving fMRI assessments examined the participants in a cognitive dissonance paradigm under conditions where they had to assert a belief contrary

to another person's belief (Domínguez, Taing, & Molenberghs, 2016). Results implicated a network of brain areas (including increased activity in a number of areas of the frontal and parietal lobes). The main findings were that expertise plays little role in a cognitive dissonance task where participants had to disagree with statements made by others, both in terms of behaviour and brain activity. As well, participants who disagreed less frequently showed stronger activation responses when they did disagree.

The Self-Perception Alternative

Cognitive dissonance theory fits some instances of attitude change, but not others. In many cases, we seem to form and change attitudes in the absence of internal discomfort. You might think, for example, that you are alert, but after yawning, you might decide, "I'm tired"—not because of a need to reduce emotional tension brought about by the discrepancy between the attitude ("I'm alert") and the behaviour (a yawn), but simply because the yawn was informative. Psychologist Daryl Bem developed the **self-perception theory** of attitude change (Bem, 1972, 2017), arguing that at times we simply infer our attitudes from our behaviours. This theory minimizes the role of emotional discomfort and suggests that when we are *uncertain* of our attitudes, we simply infer what our attitudes are by observing our own behaviour, in much the same way as outsiders might observe us. According to Bem, our behaviours are often clues from which we deduce our attitudes—for example, we might decide we like roller coasters because we keep riding them, or you might decide you now like someone from high school (whom you used to despise) because you are now pleasant to her at university. He argued that the students in the Festinger and Carlsmith study (1959) who were paid $1 would not have experienced tension but would have instead looked at their behaviour and concluded that they would not have lied for a dollar, so they must have enjoyed the task.

> **self-perception theory** a theory suggesting that when people are uncertain of their attitudes, they infer what the attitudes are by observing their own behaviour.

Which is correct—the cognitive dissonance or the self-perception explanation of attitude change? Historically, this has been a source of great debate in social psychology; however, research has clarified that each may be right, but one may be more relevant in particular situations than the other (Howe & Krosnick, 2017; Albarracín, Johnson, & Zanna, 2014). Festinger's theory of cognitive dissonance seems more applicable to situations in which we behave in ways that are strikingly out of character for us, whereas Bem's self-perception theory may be at work in situations where we behave only slightly out of character or where our attitudes are not all that clear to begin with (Albarracin et al., 2014).

Hola Images/Getty Images

"Believe what I do, not what I say." Many people who endorse healthful eating and better fitness on surveys actually consume huge quantities of junk food in their daily meals.

Do Attitudes Influence Behaviour?

If we know someone's attitudes, does that mean we can predict that person's behaviour? It turns out that the attitudes people express are not necessarily related to how they actually behave (Kroesen, Handy, & Chorus, 2017; Phillips & Olson, 2014; McGregor, 2013). (See photo.)In the 1930s, a time when many Americans held very [unacceptable] negative attitudes toward Asians, sociologist Richard LaPiere conducted a field study in which he had a couple of Chinese descent travel across the United States and visit over 250 hotels and restaurants (LaPiere, 1934). Although managers at over 90 percent of the establishments indicated in a mailed questionnaire—received prior to the actual visit—that they would not serve "Chinese" guests, only one of the establishments visited by the couple actually refused them service. In fact, most of the hotels and restaurants provided above-average service, indicating that attitudes do not necessarily predict behaviour.

Of course, sometimes attitudes do predict behaviour. Attitudes toward work and one's workplace play a strong role in job satisfaction and as such are of interest to industrial organizational psychologists as well as to organizational managers (Fletcher, Alfes, & Robinson, 2018). See the Psychology@Work video on Work Attitude to see how this is done. Research has uncovered various factors that affect the extent to which attitudes will predict behaviours (Ajzen, Fishbein, Lohmann, & Albarracin, 2018; Baumgaertner, Tyson, & Krone, 2016; Rocklage & Fazio, 2014). One of the leading factors is *attitude specificity*. The more specific an attitude, the more likely it is to predict behaviour. If a woman specifically loves the music of Adele, for example, she is more likely to download Adele's new work the first day it is released than someone who loves soul or pop music more broadly. Another factor is *attitude strength*. Stronger attitudes predict behaviour more accurately than weak

or vague attitudes. For example, people who feel passionately about gay rights are more likely to join a demonstration than people who are in favour of gay rights but see this as a more general issue in light of fairness and legal rights for everyone (Lewis et al., 2017; Petty & Krosnick, 2014). Before the implementation of COVID-19 distancing requirements and the closure of schools in 2020, it was generally accepted in the Canadian population that "good" parents restricted the screen time of their children, which is recommended in such resources as the Canadian 24-hour Movement Guidelines (Tremblay et al., 2016, 2017) publications from regional health agencies (Fraser Health, 2018; Government of Alberta, 2020), which generally recommend no screen time for children under 2 years of age, up to 1 hour of screen time a day for those 2 to 4 years of age, and up to two hours for those aged 5 to 17. During COVID-19 restrictions, with children and parents being at home, and parents attempting to work from home, many parents were finding it impossible to maintain these guidelines (Bell, 2020) and were experiencing significant discomfort as a result. Subsequently, there came about a plethora of publications "modifying" screen time requirements slightly, expounding upon how it wasn't the amount of screen time, but the type of screen time, that was to be watched for, and, eventually, reassuring parents that allowing their children to stay in front of screens for large portions of the day was in no way problematic (Cheng & Wilkinson, 2020; Dell'amore, 2020). These later publications were slightly different in tenor than those that initially came out (Bischof, 2020). Think about how this sequence of events relates to what you have just learned about Cognitive Dissonance Theory, the Self-Perception alternative, and the holding, and alteration, of attitudes? Do you think screen time will be viewed differently by the public once the pandemic is over?

Video **PSYCHOLOGY@WORK**

Work Attitude **This video looks at the industrial/organizational psychology research into the role of attitudes in relation to job satisfaction and employee retention.**

Are People Honest About Their Attitudes?

One reason that attitudes fail to consistently predict behaviours is that people often *misrepresent* their attitudes. In fact, analyses of most self-report questionnaires—the tools usually used by researchers to measure attitudes—cannot distinguish genuine attitudes from false ones (Gaete, Gómez, & Benavides, 2018; Rasmussen, Grubbs, Pargament, & Exline, 2018; Eckman et al., 2014; Rosenberg, 1969). Why would people misrepresent their attitudes? There appear to be several reasons.

The Social Desirability Factor

Often, people state attitudes that are *socially desirable* rather than accurate. A person who privately does not trust people of a particular ethnic background, for example, may not acknowledge having this attitude for fear of being judged unfavourably by others (Krumpal, 2013). To eliminate the social desirability factor and measure people's genuine attitudes, some psychologists have employed the *bogus pipeline* technique (Jones & Sigall, 1971). Here, a research participant is connected to a physiological monitoring device such as a

polygraph (a lie-detector machine that measures physiological arousal) and is told that the device can detect deception. Participants believe the machine to be functioning and also believe that it can identify dishonesty. Therefore when individuals are connected to such a device, they are more likely to report their attitudes truthfully (Morawski & Donahue, 2017; Mitchell & Tetlock, 2015).

For example, investigators ask participants about socially sensitive issues, such as how frequently they drink, smoke, have sex, and use illicit drugs (Myers, 2016; Sonon et al., 2016; Tourangeau, 2014). Participants in one group were hooked up to a device and told that the device could detect inaccurate answers. The students hooked up to the machine reported performing socially sensitive behaviours relatively frequently. Control participants, who were not hooked up to the device, answered in more socially desirable ways, reporting lower frequencies of the behaviours in question. In another bogus pipeline study, Fisher and Brunell (2014) measured gender differences in cheating behaviour. Gender differences were diminished when participants believed that their responses were being monitored by a polygraph.

Implicit Attitudes

Another problem that researchers run into when trying to measure attitudes is that people are not always *aware* of their true attitudes (Berger, 2020; Dunham, Baron, & Banaji, 2016; Leavitt, Zhu, & Aquino, 2016). In their own minds, employers may believe that applicants of all ethnicities deserve a fair interview process. But when interviewing individuals from ethnic backgrounds other than their own, the same employers may, in fact, engage in less eye contact, maintain greater physical distance, and offer less interview time than when interviewing applicants whose backgrounds are similar to their own. In such cases, the employers may have difficulty trusting people of different backgrounds, but this attitude has not reached their conscious awareness (Foley & Williamson, 2019; Schlachter & Rolf, 2017). When attitudes such as these lie below the level of conscious awareness, they are called **implicit attitudes**.

implicit attitude an attitude of which the person is unaware.

The finding that people have implicit attitudes is reminiscent of the following observation by the famous Russian writer Fyodor Dostoyevsky:

> *Every man has reminiscences which he would not tell to everyone but only his friends. He has other matters in his mind which he would not reveal even to his friends, but only to himself, and that in secret. But there are other things which a man is afraid to tell even to himself, and every decent man has a number of such things stored away in his mind.*
>
> —White Nights and Other Stories (1918)

As you might imagine, measuring attitudes that the holder is not aware of presents a challenge for researchers. To get at implicit attitudes, researchers have employed one of several measures for assessing attitudes, the *Implicit Association Test (IAT)*. The IAT uses a person's reaction times to measure the strength of the implicit associations people have in their minds. The test consists of four stages.

First, a person is exposed to two broad categories—say, "dog" and "cat." The person is

asked to categorize certain words as belonging in the "dog" category or the "cat" category—for example, fire hydrant and litter box. If the word "fire hydrant" came up and the person saw this word as more dog-related, the person would click the left button. If the word "litter box" came up and the person saw this word as more cat-related, the person would click the right button. How quickly these decisions are made is measured by reaction time—that is, how long it took to decide which button to press—the right one or the left one.

Next, the person is asked to complete a different task in which they must categorize words as either pleasant or unpleasant. These words are again fairly obvious, such as "poison" and "happiness." Again, a right or left button press is used and reaction time is measured.

Next, the categories are combined in a third task, combining, for example, dog and pleasant and cat and unpleasant. The person is asked to identify a series of words as either more dog/pleasant or more cat/unpleasant. Again, a right or left button press is used and reaction time is measured.

The categories are then reversed to be cat/pleasant and dog/unpleasant. Again, a right or left button press is used and reaction time is measured. The assumption is that if a person implicitly believes that dogs are more desirable than cats, the person should be quicker to identify pleasant words during the dog/pleasant combination, because the association between pleasant things and dogs is stronger. It will take this person slightly longer to make the dog/unpleasant association because it requires more effort. Similarly, cat people should respond quicker to the cat/pleasant combination.

If you want to see how an Implicit Association Test works, go online to https://implicit.harvard.edu/implicit/takeatest.html and take one for yourself. You can be part of a research study with tens of thousands of participants.

You might find this logic convoluted and hard to accept. However, researchers have found that many Caucasian Americans who characterize themselves as not prejudiced have quicker reaction times to Caucasian American/pleasant and African American/unpleasant identifications than to Caucasian American/unpleasant and African American/pleasant ones. Such implicit attitudes appear to be stable over time, and they have been useful predictors of both subtle indicators of discomfort, such as turning one's eyes away during a conversation with someone of another race, and overt acts of racism, such as the use of slurs, physical violence, and snubbing (Baston & Vosgerau, 2016). Researchers have also used the IAT to detect bias against gender, elderly people, overweight people, women, the disabled, and other groups (Gould et al., 2019; Babcock et al., 2016; Dunham et al., 2016; Williams & Steele, 2016; Hinman et al., 2015).

Bertram Gawronski and his colleagues at the University of Western Ontario have investigated different approaches to reducing both implicit and explicit components of prejudiced beliefs. They have found that diversity training and guided exposure to the groups toward which prejudiced beliefs are directed work to reduce explicit prejudiced beliefs, while fear reduction and other emotion-focused interventions work best to reduce implicit aspects of prejudice (Gawronski, 2019; Gawronski & Brannon, 2019; Gawronski & Bodenhausen, 2014).

Gawronski's key finding is that simple, one-element efforts to reduce prejudice do not work. Instead, he argues that a multiple component effort would be more effective if it focused on several of the following options: listening to persuasive messages arguing against prejudiced views toward a particular group; having people write arguments supporting an unprejudiced perspective; and trying to reduce the affective reaction associated with a particular group by presenting information about them in neutral or non-affect associated situations. Gawronski's research has demonstrated that combinations of these sorts of approaches result in more positive changes in participants' prejudicial cognitions and emotions (Gawronski, 2020, 2012; Hahn & Gawronski, 2019; Gawronski & De Houwer, 2014). The discriminatory treatment of Indigenous persons within Canadian society (Currie et al., 2012; Ly & Crowshoe, 2015; Pendakur & Pendakur, 2011) suggests prevalent negative attitudes toward this group. Given what you have just learned about implicit and explicit attitudes and strategies to change these, what thoughts do you have about the sorts of things various institutions or levels of government might do to try and address these issues? Think back to high school. Did you take an Indigenous studies class? Did your school promote cultural days, or Indigenous awareness days? Were you required to write any essays or commentary supportive of Indigenous experiences? The Canadian federal government has developed and anti-racism strategy (Canadian Heritage, 2019) that seeks to engage with provinces and territories and communities and to raise public awareness and shift attitudes. At this point there is still some distance to go. Consider Pendakur and Pendakur's (2011) findings that increased size of the Indigenous population in Canada did not result in a lessening of the wage differentials between Indigenous and non-Indigenous people. Given Gawronski's finding that single one-element efforts do not produce significant change, it seems clear that a broader range of initiatives are needed if there are to be significant reductions in negative attitudes towards Canada's Indigenous peoples.

Stereotypes and Prejudice

Although Hurricane Katrina, which hit Louisiana in 2005, occurred when many of you were very young, it remains a very important and controversial time in American history. Hurricane Katrina was one of the deadliest hurricanes in the history of the United States. Almost 2000 people died—many of them poor and many of them African American. In the wake of Hurricane Katrina, millions of people began reaching out with contributions and charity to help the people suffering. During a special charity drive, which aired on most major television networks, rap star Kanye West made the following statement about the disaster:

> *I hate the way they portray us in the media. You see a black family, it [the media] says, "they're looting." You see a white family, it says, "they're looking for food." And, you know, it's been five days [waiting for federal help] because most of the people are black. . . .*

In part, West was talking about *stereotypes*. Most of us are familiar with the notion of **stereotypes**—generalized impressions about people or groups of people based on the social category they occupy. Stereotypes can be based on age, race, and region of origin, as well as political or religious beliefs, or any other group characteristics.

stereotypes fixed overgeneralized and oversimplified beliefs about a person or a

group of people based on assumptions about the group.

Although stereotypes may be positive or negative, there is little doubt that there is a strong relationship between stereotypes and **prejudice**—negative feelings toward individuals from another group. Both stereotypes and prejudice lead to discrimination, which is a negative behaviour or action aimed at an individual or a specific group of individuals (see photos). Americans are not the only residents of this continent to exhibit prejudice as a result of stereotyping. First Nations peoples were exposed to bias during the Alberta floods of 2013. When Indigenous people responded with a lack of enthusiasm to the restrictions placed upon their "aid," they were criticized for being ungrateful, whereas when non-First Nations communities displayed a similar lack of enthusiasm, it was the government, not the communities, that was presented in the media as behaving inappropriately, by providing inadequate support to deserving communities in need (Thurston & Schill, 2015). For another perspective on these issues consider Indigenous Experiences 13.1.

prejudice negative and unjust feelings about individuals based on their inclusion in a particular group.

In spite of Canada's claims that we have achieved acceptance of multiculturalism and diversity (Porter, 2015; Poolokasingham, Spanierman, Kleiman, & Houshmand, 2014; Blake, 2013), Indigenous peoples are not the only peoples to experience insinuative biases. In addition to the long history of prejudice, negative attitudes, and discrimination toward our First Nations populations (Lashta, Berdahl, & Walker, 2016; Nesdole, Lepnurm, Noonan, & Voigts, 2015; Clark et al., 2014), we also demonstrate bias against those of other races and ethnicities (Blake, 2013; Poolokasingham et al., 2014; Porter, 2015; Zellars, 2016), and of different religions. Anti-semitism, for example, is a problem not only globally but also within Canada, (Hollinger, 2020; Robinson, 2015) and a study by Zafar and Ross (2015) found attitudes in Canada toward those of the Muslim faith to be particularly negative. Attempts to manage discrimination through legislation have been imposed with debatable effects (Hollinger, 2020).

Racial bias **In the aftermath of Hurricane Katrina, newspapers carried many photos of desperate and hungry people taking food from local food stores. The news caption that accompanied the photo on the left (of an African American) stated that the man had just finished "looting a grocery store," whereas the one that accompanied the photo on the right (Caucasian Americans) said that the two individuals had just finished "finding bread and soda at a local grocery store."**

13.1 Indigenous Experiences

Stereotyping and the "Sixties Scoop"

Following World War II, the Canadian government took over the administration of residential schools. To that point, many schools had been providing only rudimentary educations at best. After that, instead of schools, they began to largely function as institutions for Indigenous children that the government deemed to be receiving inadequate care at home (Truth and Reconciliation Commission of Canada, 2015). Around this same time, government social service agencies lobbied for changes to the Indian Act and, in 1951, amendments were made that enabled provincial departments of health, welfare, and education to have jurisdiction on reserves (McKenzie, Varcoe, Browne, & Day, 2016). Provincial governments differed in the agreements they signed with the federal government outlining how on-reserve welfare programs would operate and be funded, but none supported preventive services that would help families remain together (Sinha & Kozlowski, 2013).

It is important to note that many scholars recognize that "good intentions" lay behind these changes, but one scholar adds that "little attention was paid to the effect that extending provincial services would have on Indian families and communities"

(Johnson, 1983, p. 3). However, stereotypic thinking of what was in the best interests of children played a significant role in the events that followed. "Indigenous children often were apprehended because of incongruences between Euro-Western [stereotyped] notions and cultural practices [about "good" parenting] and the realities of Indigenous communities…. [and] did not consider the long-term effects of child apprehension on children, their families, and their communities" (McKenzie, et al., 2016, pp. 6–7).

In what was later labelled "the Sixties Scoop," beginning in the 1950s and 1960s, and extending into the 1980s, the government of Canada implemented a wholesale foster and adopt program for Indigenous children (Fachinger, 2019). Many Indigenous children were forcibly removed from their homes of origin and placed in foster or adoptive homes with non-Indigenous families. These "protection" practices intensified the hurt perpetrated by the residential school system. Countless children experienced abuse and neglect in the homes in which they were placed (Truth and Reconciliation Commission of Canada, 2015). Even those children placed in nurturing and loving homes were affected by discrimination and racism and suffered from being placed in permanent care away from their own families and communities. The consequences of such actions were far reaching and affected every aspect of the lives of the children, the families who lost their children (often without their knowledge or consent), and subsequent generations (McKenzie et al., 2016).

THE CANADIAN PRESS/Jason Franson

Sixties Scoop Survivors of the "sixties scoop" and their families prepare to hear then Alberta Premier, Rachel Notley's apology at the Alberta Legislature, in Edmonton, Alberta.

The late author and journalist, television broadcaster/producer and documentary producer, Richard Wagamese, an Anishinaabe (Ojibwe) from the Wabaseemoong Independent Nations in Ontario, and a survivor of foster care, wrote an essay entitled "Surviving the Scoop." In it, he said, "[T]his sad chapter [the Sixties Scoop] in our country's history followed closely on the heels of the closure of the residential schools. To those affected, the Scoop felt like a continuation of the same genocidal policy. For me, it meant the door was effectively slammed shut on my identity" (as cited by

Fachinger, 2019, p. 118).

Critical Thinking Questions

In what ways did stereotypic thinking interact with the "good intentions" behind the huge jump in the numbers of Indigenous children in foster care during the "Sixties Scoop?"

How might the cultural experiences of Indigenous children be impacted by their being fostered or adopted by non-Indigenous families?

In what ways were the Sixties Scoop and residential school experience similar?

Some psychologists believe that the human tendency to identify with a group is one of the main contributors to stereotypes and prejudice (Sherif, 1967; Dovidio, Schellhaas, & Pearson, 2019). Evolutionary psychologists believe that as humans, we generally categorize ourselves in terms of our similarities to some people and our differences from others. Sometimes referred to as the *mere categorization effect* (Zajonc, 1968), it has come to be accepted that the mere act of categorizing individuals into groups causes them to identify themselves as "us" or "them." Understanding ourselves as members of a particular group (our *in-group*) offers us some insight into who we are. Similarly, perceiving people outside our group as members of other groups (*out-groups*) gives us information—not necessarily valid information—about who they are. This basic categorization structures our future perceptions. Denis Krebs at Simon Fraser University argues that we then use this basic categorization to identify with those we favour and with those we choose to discriminate against (Krebs & Denton, 2014). Since we view those in the out-group as different than ourselves or our in-group, Krebs argues that we therefore feel very little empathy for those in the out-group and thus feel justified in discriminating against them.

The Robbers Cave experiment The Robbers Cave experiment is a classic study of group formation.

Source: From "The Robbers Cave Experiment" by M. Sherif, O. J. Harvey, B. J. White, W. R. Hood, and C. W. Sherif, Wesleyan University Press, 1988, p. 103.

Evolutionary psychologists suggest that stereotypes and prejudice may have had some adaptive value, as our ancestors probably prized being able to quickly recognize members of their own tribe based on superficial information (Simpson & Kenrick, 2013). Early humans needed to quickly identify other figures as friends or foes, and general appearance would have been an easy way to accomplish this goal. Evolutionary psychologists also suggest that we may be prewired to think of people whom we perceive to be different from us as inferior, which may cause or justify our decisions to exclude or demean them (Kteily et al., 2015; Durante et al., 2013).

A view called the *realistic conflict theory* argues that competition arises between different groups because of conflict over scarce resources (Jackson, 1993; McKenzie & Twose, 2015). A classic study, Sherif's Robbers Cave Experiment, illustrates this theory (see photo). Remember that according to this theory, the amount of actual conflict between particular in-groups and out-groups determines the degree of prejudice or discrimination between those groups. A group of 22 11-year-old boys were taken to a camp in Robbers Cave State Park in Oklahoma. The boys were randomly divided into groups before leaving for camp. The groups were housed separately and did not know of the existence of the other group. Each group chose a name ("Rattlers" and "Eagles") and they put the name on their shirts and flags. After a week the two groups met and engaged in a series of competitions against one another. The Rattlers were the winners. The two groups began to call one another names, refused to eat in the same room, and engaged in a series of negative behaviours

toward one another. Having deliberately sowed the seeds of discontent, the experimenters then worked to see if the boys in the two groups could overcome their animosity. A series of problems arose that required that all of the boys work together to overcome them (contaminated drinking supply, etc.). The boys began to eat together once more and when the time came to leave, they voted to take the same bus home (Sherif, 1961). This study gave people hope that peace could flourish between former enemies if they were able to exceed the boundaries of their individual groups. Indeed, data suggest that forming emotional ties to those we stereotype can actually create a positive change in attitude, creating warmer, more emotional links to individuals previously stereotyped (Sevillano & Fiske, 2016).

Another view, **social identity theory**, suggests that in social situations individuals often identify as a member of the group (Tajfel, 2010; Trepte & Loy, 2017). They see themselves at times as a group member rather than as an individual (Langner & Wiedmann, 2015). Social identity theory proposes that prejudice emerges through three processes:

Social categorization, in which a person affiliates with a particular group as a way of figuring out how to act and react in the world.

Social identity, in which the person forms an identity within the group.

Social comparison, in which the group member compares the group favourably with other groups, and in turn derives a sense of positive well-being from looking at himself as superior in some way.

social identity theory a theory that emphasizes social cognitive factors in the onset of prejudice.

In one of his early studies, Tajfel (1981) randomly assigned study participants to two groups and then had them decide how to divide a sum of money between two people identified only by their group membership and an ID number. Participants typically showed what Tajfel called an in-group bias by giving more of the money to the person in their group than the person in the other group. Even with no group interaction, the effects of social categorization, social identity, and social comparison can be seen in this result. Now think back to the in- and out-group environment that was probably evident in your high school, and see if you can identify examples of social behaviour that reflect the three central factors of social identity theory just discussed.

Attitudes and the Power of Persuasion

Earlier, we discussed how attitudes form and change. Advertisers have taken a strong interest in these processes. In fact, billions of advertising dollars are devoted each year to helping people develop particular attitudes toward products or services. If you wouldn't dream of using any computer but a MacBook Pro® (or Air®), or if you much prefer Coke® over Pepsi® (or vice versa), that attitude probably has been created in part through persuasion—the advertiser's best efforts to convince you that its product is far superior to anyone else's and that you must have it. Politicians running for office, interest groups looking to increase their influence, and any number of others also regularly use persuasive techniques. Indeed, most of us have had occasion to try to persuade someone else to come

around to our way of thinking.

For persuasion to occur, a few elements must be present (Petty & Cacioppo, 1986). There must be, of course, a *message*, somebody to transmit the message (the *source*), and somebody to receive it (the *receiver*). In attempting to make a message persuasive, the source can use methods that follow either a central route or a peripheral route (**Figure 13.3**). While Petty and Cacioppo's original research examined responses to televised speeches about nuclear armaments by American President Ronald Reagan and Soviet Premier Mikhail Gorbachev, the same key elements can be found in guides offered more recently for how to become a social media influencer (Lou & Yuan, 2019).

Central Route versus Peripheral Route

The *central route* to persuasion emphasizes the content of the message, using factual information and logical arguments to persuade. This method requires a fair amount of effort on the receiver's part and is more commonly used for matters of some significance (Petty & Cacioppo, 1986). If you were trying to decide whether to buy a Mac or a PC, you might be willing to spend considerable time in careful deliberation of all the facts. After all, a computer is an expensive item and an important purchase. You might not be as interested in thinking hard about whether to buy Coke® or Pepsi®, however, or about which brand of shampoo to purchase.

The *peripheral route* relies on more superficial information. When you respond to peripheral appeals, you are responding to such factors as how attractive the spokesperson is and how amusing or engaging the message is (Petty & Cacioppo, 1986). As might be expected, decisions based on central routes to persuasion are more likely to last than decisions based on the peripheral route.

Aids to Persuasion

Beyond the route chosen, a number of other factors can also make a message more or less persuasive. Characteristics of the *source* are important (Petty & Cacioppo, 1986). We are more likely to be persuaded by a source who is rated as more knowledgeable or more likeable, for example. In addition, if we think of the source as more similar to us, we are more likely to be persuaded by the message. (This is part of the reason why wealthy political candidates often try to emphasize their middle-class roots by speaking in shopping malls and grocery stores.) Finally, at least in some instances, people are more likely to find a source credible and persuasive when the source presents both sides of an issue (Clark & Evans, 2014).

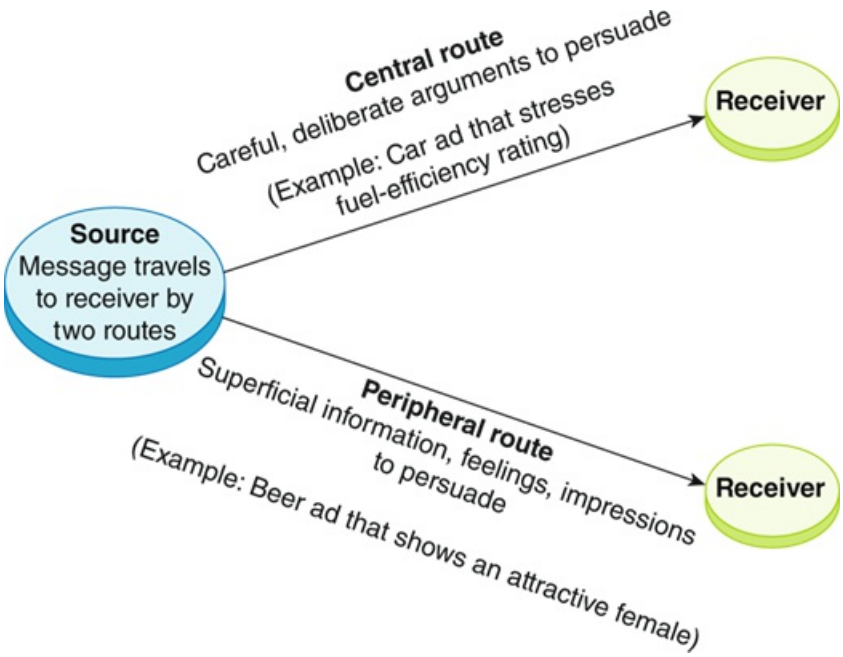

FIGURE 13.3 Two routes to persuasion

Sometimes the key to persuasion rests on an interaction between audience characteristics and source characteristics. If, for example, a source is trying to win the favour of an intelligent or highly motivated audience, an emphasis on logic and on supporting data is more likely to carry the day (see photos). If addressing a less intelligent or less interested audience, however, the source might have more success with a glossy, superficial presentation and a good haircut.

Rachel Megawhat/Alamy Stock Photo

Tetra Images/Getty Images

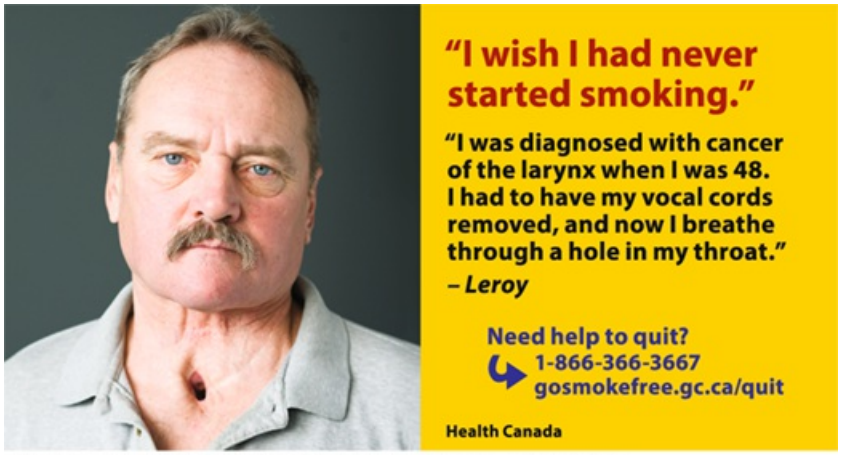
Tools of persuasion The organization People for the Ethical Treatment of Animals (PETA) has run many campaigns to persuade consumers to stop eating meat and become vegan. Which of these approaches is more likely to help change the minds of meat eaters—the image of protesters lying naked smeared in a blood-like substance (left), or the spokesperson who systematically presents facts and figures on the merits of a vegetarian lifestyle (right)?

A number of *specific techniques* can further improve the chances of successfully persuading others (Dolinski, 2015). We will mention three here. You have probably been exposed to all of these strategies (and you may have even used them).

The *foot-in-the-door technique* involves getting someone to agree to a small request and then following up with a much larger one (Mitchell & Tetlock, 2015). The idea is that a bond has been forged between the requestor and the requestee, so the requestee will be inclined to grant the second request because of having granted the first one. For example, you might first ask to borrow your friend's truck to move some furniture for an afternoon, and then later ask to borrow it for the entire weekend as the move is taking longer than you had anticipated. Having already granted the smaller request your friend is more likely to agree to the much larger request. Why? Recall our earlier discussion about cognitive dissonance. We strive to be consistent. Your friend made a decision to help you with your move and so now does not want to go against that earlier decision by turning down your larger request. Scammers use this technique to bilk money from gullible lonely singles or seniors, starting with small requests and then escalating (Whitty, 2013).

The *door-in-the-face technique* reverses this behaviour. The technique involves making an absurd first request that will obviously be turned down, and then following it with a more moderate request (Henderson & Burgoon, 2014). Here the idea is that if the first request is turned down, the requestee feels guilty and so is more likely to comply with a second, more reasonable, request in order to reduce the guilt. For example, a teenager might wake a parent who is napping to ask her parent to drive her to a friend's place across town. When the parent replies that they are obviously resting, the teen follows with a request for money for a cab. The door-in-the-face technique works because a person (the parent in this case) feels guilty for turning down the first request and may fear rejection based on their decision. Thus, complying with the second request allows a person to alleviate their guilt and relieve concerns about social rejection.

Appeals to fear can be powerful. We frequently see these appeals in anti-smoking campaigns (Cummings, 2020; Nabi & Myrick, 2019; Halkjelsvik, 2014) (see photo) and in political campaigns (Rold & Honeycutt, 2016). In order to work, however, an appeal to fear must have a credible source sending the message, and must make receivers truly believe that something bad will happen to them if they don't comply with the source's request. Most importantly, the appeal must provide the receiver with an explicit recommendation for change. For example, there is no sense in worrying about an asteroid hitting earth because there is nothing you can do about it. But if you use condoms when having sex you significantly reduce your chances of contracting HIV or other STDs. So advertisements urging you to use condoms are likely to be more effective than advertisements urging you to purchase protection from asteroids.



© Her Majesty the Queen in Right of Canada, represented by the Minister of Health (2014).

Fear as persuasion **Anti-smoking ads commonly use fear—the fear of life-threatening illness or disgusting physical outcomes—to try to persuade smokers to quit.**

Barriers to Persuasion

Other strategies can interfere with persuasion. We will mention only a couple.

Forewarning an audience that you will be trying to persuade them of something will immediately raise their defences. Although listeners in this situation may make subtle shifts toward your way of thinking, they are unlikely to change their attitudes as much as individuals who are not told that they are about to hear a persuasive speech (Weitzl, Seiffert-Brockmann, & Einwiller, 2020).

Beginning with a weak argument instead of a strong one can make subsequent arguments seem weaker (Stiff & Mongeau, 2016). For example, a child arguing for an advance on their allowance and arguing by saying she wants the money to buy some candy might lead the parent to interpret a subsequent argument—that the child gave money to a friend at school who had no lunch—as more of an excuse than a valid argument.

Before You Go On

(Answers to Before You Go On may be found online in the Course Resources.)

What Do You Know?

1. What are the three components of attitudes, according to the ABC model?

2. How do cognitive dissonance theory and self-perception theory differ in their explanation of attitude change?

3. Overall, are Canadians holding negative implicit or explicit attitudes toward Indigenous Canadians and if so how should the government direct efforts to manage attitudes toward Indigenous peoples in Canada?

4. Why do people sometimes misrepresent their attitudes?

5. How does social identity theory explain prejudice?

6. What are the central and peripheral routes to persuasion?

What Do You Think? • Watch a television advertisement or select a print ad and critique it according to the material in this section. For example, does the advertisement use the central or the peripheral route? Was that a good route for the advertiser to choose, considering the product being advertised?

Social Cognition: Attributions

LEARNING OBJECTIVE 2

Discuss how people make attributions to explain their own behaviour and the behaviour of others.

In many ways, we are all lay psychologists, continually trying to explain what we see in our social worlds so that we can make sense of events and predict what will happen in the future. We attempt to figure out *why* people, including ourselves, do things. Social psychologists refer to these causal explanations as **attributions**, and they are interested in what influences our attributions and how such attributions affect our subsequent decisions, feelings, and behaviours (van Noorden et al., 2016; Smith, Mackie, & Claypool, 2014).

attributions causal explanations of behaviour.

Dispositional and Situational Attributions

Attributions fall into one of two categories. *Dispositional*, or *internal*, attributions focus on people's traits as the cause of their behaviour (Försterling, 2013). In contrast, *situational*, or *external*, attributions focus on environmental factors as the cause of behaviour (Sultan & Hagger, 2014; Försterling, 2013).

Social psychologist Lee Ross (2018, 2001, 1977) has referred to our reliance on dispositional attributions to explain the behaviour of other people as the **fundamental attribution error**. When we are almost hit by a speeding driver, we are likely to conclude that the driver is reckless and irresponsible, even though, in fact, she might have been racing to the hospital to see a stricken child. When we meet a woman who is not very talkative, we may conclude that she is withdrawn and arrogant, when in fact she might be a normally friendly sort who has a terrible cold. When a professor provides unsatisfactory lectures, we may assume that he is disorganized or incompetent, when in fact he may be a single father struggling with an autistic child or may be constrained by the policies of the university (Moran, Jolly, & Mitchell, 2014).

fundamental attribution error the tendency to use dispositional attributions to explain the behaviour of other people.

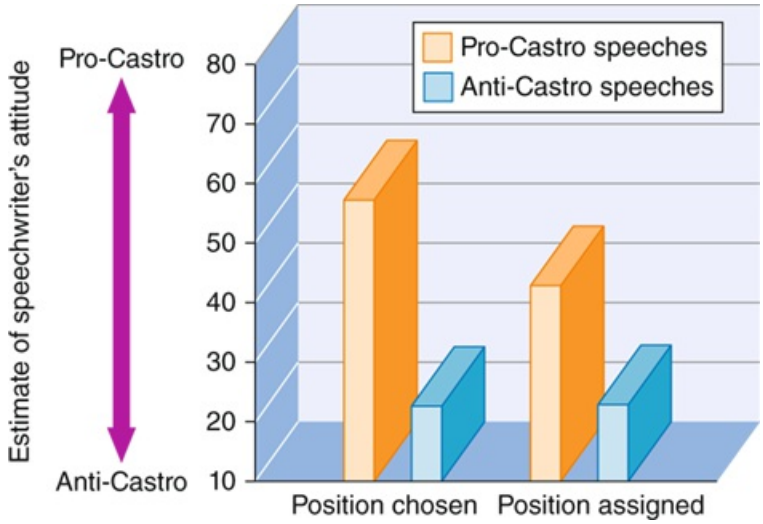


FIGURE 13.4 The fundamental attribution error Even when told that pro-Castro or anti-Castro speechwriters had been randomly assigned their positions, research participants assumed that the speechwriters truly believed what they had written (Jones & Harris, 1967).

Source: Adapted from Myers, D. G. (2002). Social psychology (7th ed.). New York: McGraw-Hill, Figure 3-2; data from Jones, E. E., & Harris, V. A. (1967). The attribution of attitudes. Journal of Experimental Social Psychology, 3, 1–24.

What determines whether we make dispositional or situational attributions? Research suggests that when explaining *other* people's behaviour, we tend to rely more heavily on dispositional attributions. In a classic study from the 1960s, researchers had participants read a speech that expressed either support for or opposition to Cuban leader Fidel Castro. They then asked each participant to rate the extent to which the speechwriter was pro-Castro (Jones & Harris, 1967). Participants who read a speech supportive of Castro naturally rated the speechwriter as pro-Castro, and those who read a speech critical of Castro naturally rated the speechwriter as anti-Castro. These were dispositional attributions; the participants reasoned that the speeches reflected internal characteristics of the speechwriters. But then the participants were told that the speechwriters had been randomly assigned to write either a pro- or anti-Castro speech. In other words, the participants were given a reason to make a situational attribution rather than a dispositional one. Remarkably, even with this knowledge, the participants rated speechwriters who had written supportive speeches as very pro-Castro and speechwriters who had written critical speeches as very anti-Castro (see **Figure 13.4**), indicating that we do not use situational information even when it is available.

However, we can learn not to make the fundamental attribution error—or at least to make it less often. Research indicates that automatic stereotyping and prejudice are reduced when participants are exposed to the Situational Attributional Training Technique. The essence of this training is to get people to consider the external causes for someone's

behaviour rather than to immediately jump to making an unfavourable dispositional attribution (Rachmawati, Purwanto, & Awalya, 2018; Hooper et al., 2015). We make the fundamental attribution error because information about the situations of other people is often difficult to get and even more difficult to use and so we fall back on an easier dispositional attribution. However, the work by Hooper and colleagues suggests that we can learn to use situational information if we make the effort to take the perspective of another person.

The Actor–Observer Effect

Social psychologists refer to the discrepancy between how we explain other people's behaviour and how we explain our own behaviour as the **actor–observer effect** (Jones & Nisbett, 1971). The idea of the actor–observer effect is that as *actors*, we tend to make situational attributions about our behaviours; and as *observers*, we tend to make dispositional attributions about the behaviour of others (**Figure 13.5**). For example, as an actor, if we skid into a ditch and get stuck in the deep snow we will most likely make a situational attribution, "The roads are so icy, I never had a chance." However, if we witness the identical situation with another person we make an internal attribution, such as, "She was probably driving way too fast." In this instance, as the observer, we view the other person as having been careless—an internal attribution. Several explanations have been offered as to why this is so (Forgas & Williams, 2014). For one thing, as actors, we have information about ourselves that observers don't have. We know from experience, for example, that we don't act the same way in every situation; we know, for example, that we typically drive carefully and do not regularly skid off the road. For another thing, observers tend to focus on the actor, while actors need to focus more on situations. Consider your response as you watch a fellow student give a very bad presentation. You (as the observer) have no information beyond what you can see. What you see is a disorganized, rambling talk that conveys very little understanding. However, the fellow student (the actor) knows that her situation is beyond her control. She was exceptionally prepared but upon arriving at school saw her partner embracing another person and was therefore too distressed to give the presentation coherently. Interestingly, if people are shown videotapes of their own behaviour—that is, if they become observers—they tend to make more dispositional attributions (i.e., make the fundamental attribution error) about the causes of their behaviour (Storms, 1973). That is, the video enables them to switch from actors to observers, and their explanations for their behaviours switch correspondingly.

> **actor–observer effect** the discrepancy between how we explain other people's behaviour (dispositionally) and how we explain our own behaviour (situationally).

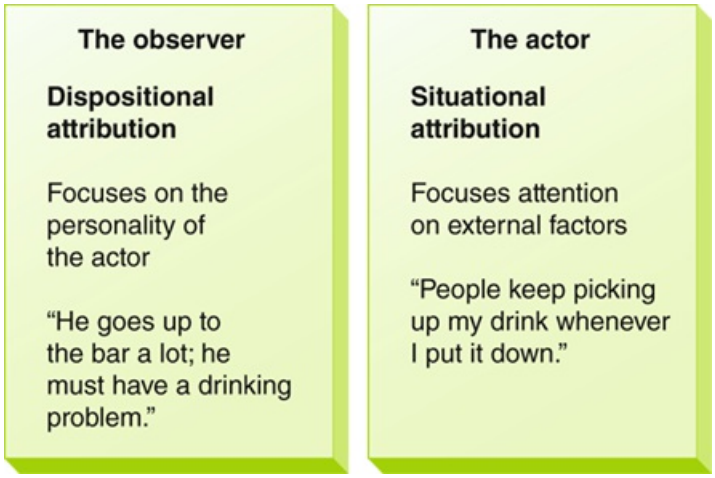

FIGURE 13.5 The actor–observer effect We tend to explain our own behaviour in terms of external factors (situational attributions), and others' behaviour in terms of their internal characteristics (dispositional attributions).

The actor–observer effect is a problem because it is an attributional bias that affects how we perceive and interact with others. When we make dispositional attributions about other individuals we engage in stereotyping, and stereotyping often leads to misjudging others. Note that we are most likely to make dispositional attributions about others when outcomes are negative. What sort of attributions do we make when the "person" we are interacting with is not human? That may sound like a stupid question but about when we are interacting with an artificial intelligence managed robot like Sophia. To find out about Sophia have a look at Your Brain and Behaviour 13.1.

13.1 Your Brain and Behaviour

Facilitating Robot–Human Interactions and Avoiding the "Uncanny Valley"

Robots are here and will likely become even more commonplace in our everyday existence over the next two decades. Robots currently vacuum our floors, answer our doorbells, and even drive our cars. Of course, when we think of robots we don't often think of Roombas, Alexa, or a Tesla. Rather, we think of machines that look more like us. On October 25, 2017, Sophia (see photo on next page), one of many human-like robots that have been made by Hanson Robotics, was given Saudi citizenship in Riyadh, Saudi Arabia. Looking at the photo of Sophia, it is obvious that her features are eerily similar to our own. With hair, she may even be able to pass us on a busy city street without any of us noticing that she is not human.

Researchers in neuroscience and robotics are keenly interested in how our brains respond to how robots look (Henschel, Hortensius, & Cross, 2020; Rosenthal-von der Pütten et al., 2019; Rosenthal-von der Pütten & Krämer, 2014). One aspect of robot development, and our liking of them, that is often discussed in robotic circles is how to avoid the "uncanny valley." This concept was first described by Masahiro Mori (1970) but was long ignored by robotic developers and social scientists. This concept is that as

a robot begins to look more and more like us, we may no longer like it but rather find it eerie and creepy. In some cases, we may even feel repulsion. Some of you may feel this way when you look at Sophia: the lifelessness of the eyes seems to be especially important in decisions about robot likeability.

Neilson Barnard/Getty Images

To try to figure out how to avoid the uncanny valley in robotic development, neuroscientists have begun to study how our brain responds to different robotic styles. What scientists have found is that people like robots better that look like us, but when robots become too lifelike we report liking them less, and this is reflected in our brain activity. When we look at robots that are lifelike, we see changes in the activation of the brain in areas such as the ventromedial prefrontal cortex and the amygdala. When we look at robots we like, we see higher activation in each of these areas, but when we look at robots that appear to be too human, activity in both of these areas drops off and we dislike them. The uncanny valley that was proposed in 1970 seems to have its roots in the activity of our very human brain.

Questions

Which regions of the brain are most active when making decisions about whether we like a person or a robot?

What areas of the brain are activated differentially when we look at a robot and think about it experiencing pain or pleasure?

What features of a human-like robot are most likely to influence how we respond to them? What do you think humanoid robots should look like?

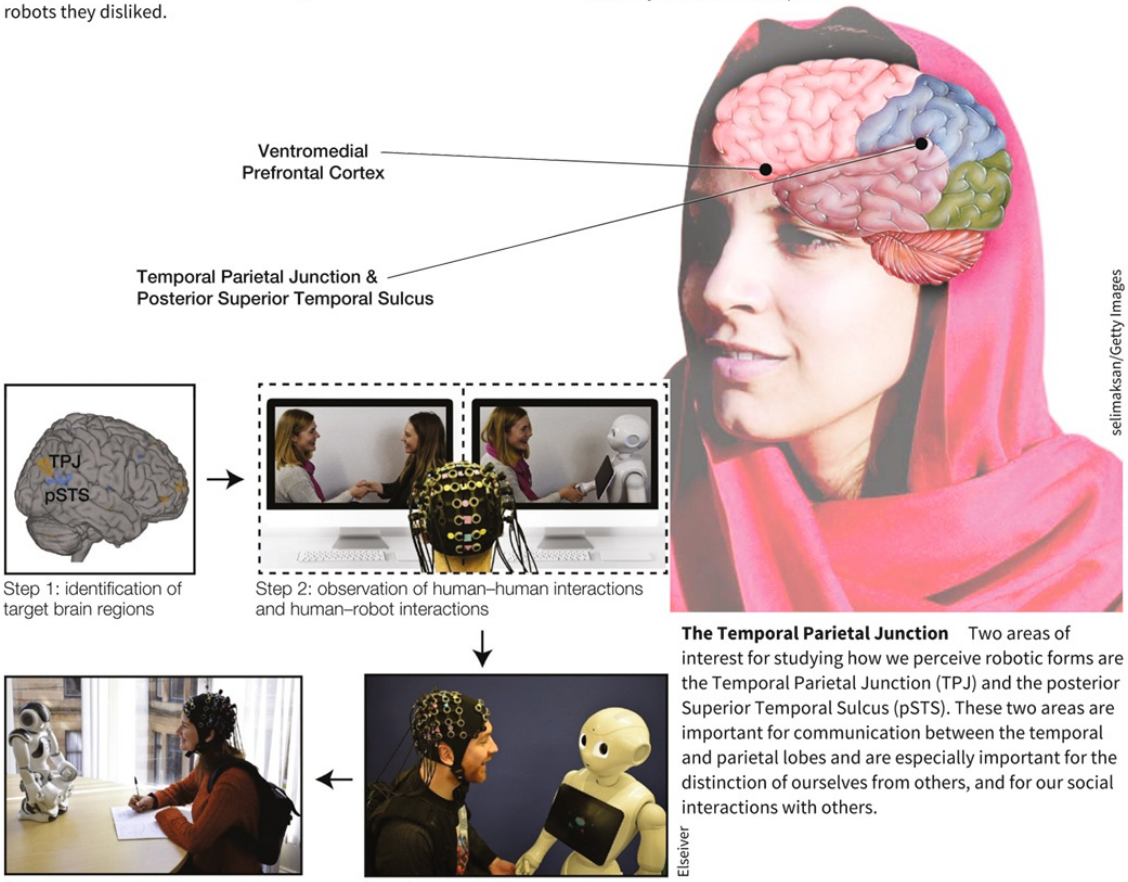
KISMET - The first robot to recognize emotion KISMET is a robot head made in the late 1990s at the Massachusetts Institute of Technology by Dr. Cynthia Breazeal (shown on the left). KISMET was one of the first robots to recognize emotions and socially interact with humans.

Rosenthal-von der Putten et al., *Journal of Neuroscience* 14 August 2019, 39 (33) 6555-6570

What do we prefer? This image taken from Rosenthal-von der Pütten (2019) shows different robotic forms. Participants were asked to rate how much they liked each of these robots. While the participants in this study reported liking the robots that appeared more human like (the middle image) they disliked the robot that appeared too human. One of the key areas in the brain for this change from like to dislike appears to be the ventromedial portion of the prefrontal cortex. Activity in this area dropped off significantly when participants viewed images of the human-like robots they disliked.

DENIS BALIBOUSE / REUTERS

Sophia - A human-like robot made by Hanson Robotics How we respond to robots or avatars in our real lives, or in virtual reality spaces, influences how we may interact with online robot counsellors, teachers and health care practitioners of the future. The study of robot-human interactions is in its infancy but data has shown that our brains like robots that are human like, but not too human. How do you feel about Sophia?



The Temporal Parietal Junction Two areas of interest for studying how we perceive robotic forms are the Temporal Parietal Junction (TPJ) and the posterior Superior Temporal Sulcus (pSTS). These two areas are important for communication between the temporal and parietal lobes and are especially important for the distinction of ourselves from others, and for our social interactions with others.

Brain activation When we study human-human or human-robot interactions we are looking for differences in the activation of the brain, using various neuroscience techniques during these interactions.

Exceptions to the Fundamental Attribution Error

Despite the trend just described, we do not *always* attribute other people's behaviours to their internal characteristics or personalities. When we know that just about everyone would react the same way in a given situation, we will likely conclude that a person's behaviour in that situation is situationally caused (Korman & Malle, 2016). When most persons are robbed at gunpoint, for example, they (wisely) hand over their money. Thus, a particular robbery victim's surrender of money will usually be attributed to powerful situational factors.

Similarly, if we are given detailed information about situational pressures, we may attribute the behaviour of other people to situational factors. Think back, once again, to the events surrounding Hurricane Katrina. Initially, most television viewers assumed that all New Orleans residents who had stayed at home rather than evacuate to another city were stubborn, or foolish, or both. However, when information later revealed that thousands of the city's residents were too poor to own a car and that all public transportation systems had shut down, most viewers shifted to a situational explanation for the residents' behaviour.

By the same token, we do not *always* attribute our own behaviour to situational factors. Let's say, for example, that you do poorly on an examination and complain that the questions were "too hard" and the grading unfair. You are, as we would expect, making a situational attribution for your poor performance. But suppose you get a good mark on the next examination. Will you explain your success by pointing out how easy the exam questions were or how generous the grading was? Not likely.

Consistent with this point, social psychologists have noted that when we explain our own behaviour, we are able, and often likely, to fluctuate between situational and dispositional attributions, depending on which puts us in a better light. In other words, we tend to attribute our successes to internal causes and our failures to external ones—a phenomenon referred to as the **self-serving bias** (Wieman & Welsh, 2016; Miller & Ross, 1975). Research also has indicated that the direction of our attributions can be influenced by factors such as our moods and emotions, motives, prejudices and stereotypes, and cultural background (Major & Dover, 2016; Newey, 2016; Rubenstein et al., 2016; Wilson & Buttrick, 2016; Tasimi & Johnson, 2015; Schwarzer, 2014; Smith, Mackie, & Claypool, 2014).

> **self-serving bias** the tendency people have to attribute their successes to internal causes and their failures to external ones.

Indeed, in some cases it would appear that the self-serving bias serves a protective function for self-esteem; for example, researchers have found that depressed individuals sometimes have a more realistic perception of themselves and their abilities, a phenomenon known as depressive realism, or the sadder-but-wiser hypothesis (Moore et al., 2016).

Before You Go On

(Answers to Before You Go On may be found online in the Course Resources.)

What Do You Know?

7. How do dispositional and situational attributions differ?

8. What is the fundamental attribution error?

9. What are some exceptions to the actor–observer effect?

What Do You Think? • How do you think empathy might influence the actor–observer effect?

Social Forces

LEARNING OBJECTIVE 3

Describe the power of conformity and obedience in shaping people's behaviour.

As bad as conditions were in the last-resort shelters after Hurricane Katrina, they were even worse in the New Orleans Convention Center. A small group of people decided to make their way to this facility, even though it had not been designated a shelter. Others followed, until the convention centre was filled with thousands of displaced souls. Those people waited for days for food and support to come. However, because the convention centre had never been formally designated a shelter, federal and state agencies did not even know anyone was there. Not until days later, when television and news reporters "found" those in the centre, were they included in the city's relief efforts.

Given the chaos and uncertainty in the aftermath of Hurricane Katrina, it is understandable that people would look for any sign of what to do or how to get help. The fact that a small group of people decisively sought shelter at the convention centre, even in the absence of any information about whether that was a good choice or not, was more than sufficient to influence many other people to seek shelter there. Even in more normal situations, *social forces* such as these exert a powerful influence on our behaviours and beliefs. (See Psychology Around Us 13.1.) Often, for example, people conform to the behaviours and opinions of others, especially when those behaviours and opinions reflect a majority position. We will discuss the social forces of conformity and obedience in this section. First, though, let's examine the related topics of *norms*, *social roles*, *conformity*, and *obedience*.

Norms and Social Roles

In the aftermath of Vancouver's 2011 Stanley Cup final loss, many people arrived downtown after the game was over to join whatever social event was going to happen. Later, people around the country learned that a growing number of "sports fans" were burning cars and breaking into stores. Such reports made most people feel very unsettled. One reason for their discomfort was that such behaviours seemed to represent a breakdown of social values and compassion. Another reason was that the behaviours defied people's social expectations. Respectable citizens are not supposed to break into stores and carry off goods, and sports fans are supposed to celebrate or mourn their team's accomplishments without setting fire to vehicles. These expectations arise from the norms and roles of our society.

13.1 Psychology Around Us

More Than Tiredness

Yawning is contagious. Try it. If you have someone in the room with you right now, yawn (or fake a yawn), and see what happens (it's even more fun if you can pull it off with a group of people). Although this effect hasn't been studied specifically in humans, researchers at Emory University (de Waal & Preston, 2017; Campbell & de Waal, 2011) were able to trigger enhanced yawning in chimpanzees by showing them film footage of other chimpanzees yawning. The effect was two times larger if the chimpanzees in the movie were familiar to the chimpanzees watching the movie. Psychologists are not sure why this happens. Is it conformity? Social modelling? Peer pressure? Many social psychologists believe that contagious yawning may be a way of binding ourselves to other members of our group—that is, the sharing of an experience. More recently researchers from Liverpool (Amici, Aureli, & Call, 2014) replicated the results of the study from Campbell et al. and were also able to show that chimpanzees were not reactive when exposed to other actions such as scratching or wiping their noses; instead, increased reactivity was limited to contagious yawning. The researchers speculate that yawning may be linked to empathy. So if you yawn and a friend or colleague yawns right along with you, don't worry—you're not boring each other; you're sharing a moment.

Norms

Society is filled with rules about how everyone is supposed to act. These conventions, referred to as **norms**, provide order and predictability. Some norms are *explicit*, or stated openly. We all know, for example, that we are supposed to stop our car when we come to a red light. Other norms are *implicit*. These norms are not openly stated, but we are still aware of them. You probably weren't taught as a child to face the front of an elevator, for instance, but when is the last time you stepped into an elevator where all the passengers had their backs to the doors?

norms social rules about how members of a society are expected to act.

Richard T. Nowitz/Corbis/Getty Images

Pictorial reminder **This sign along a Newfoundland highway reminds drivers of the deadly physics of hitting a moose. It also helps remind people of the community's injunctive norm to drive responsibly. Such reminders often have a beneficial impact.**

We can also classify norms as descriptive or injunctive (Carcioppolo, Dunleavy, & Yang, 2017; Pedersen et al., 2017; Jeffrey et al., 2016; Panagopoulos, Larimer, & Condon, 2014). *Descriptive norms* are agreed-on expectations about what members of a group *do*, while *injunctive norms* are agreed-on expectations about what members of a group *ought to do* (see photo). Consider the behaviour of museum patrons, for example. The pristine appearance of the typical museum, along with signs throughout the building, regularly remind patrons not to litter in this setting. Virtually all museum goers abide by this rule, making it a descriptive norm (Kenrick & Goldstein, 2012). Other researchers have examined how norms influence behaviours and intentions. Smith and colleagues (2012) report that when injunctive and descriptive norms were in conflict, people's intentions (in this particular case) to engage in pro-environmental behaviours were weakened.

People are more likely to abide by injunctive norms if the norms are called to their attention. For example, people walking through a neighbourhood with litter cans and anti-littering signs are more likely to become aware of and follow the community's injunctive anti-littering norm. Simons-Morton et al. (2014) examined the effects of social norms on risky driving among adolescent males. Adolescent males were accompanied in a driving simulator by an age-matched peer who was either a risk-averse confederate or a risk-accepting confederate. Results indicated that adolescent males were more likely to engage in risky driving behaviours when accompanied by a risk-accepting peer. These results suggest a strong role for social influence in risky adolescent driving and indicate that some of the variability in adolescent driving can, in part, be accounted for by injunctive norms.

Social Roles

A **social role** is a set of norms ascribed to a person's social position—expectations and duties associated with the individual's position in the family, at work, in the community, and in other settings (Scheibe & Barrett, 2017; Yao & Moskowitz, 2015; Sarbin & Allen, 1968). The role of police officers, for example, is to maintain law and order. The role of parents is to nurture, rear, and teach their children and prepare them for life outside the family.

> **social role** a set of norms ascribed to a person's social position—expectations and duties associated with the individual's position in the family, at work, in the community, and in other settings.

Roles often have a positive impact on people and society. Indeed, they are critical for the smooth functioning of society. They can, however, also confine people. Just as many actors complain of being "typecast" and prevented from demonstrating their versatility, people in various positions are often limited by their prescribed social roles. Many observers argue, for example, that traditional Western gender roles are oppressive for women.

When individuals in a particular group try to step out of the social roles assigned to members of that group, they may be met with negative reactions and evaluations (Story et al., 2020; Clow, Ricciardelli, & Bartfay, 2014). For example, traditional Western gender roles ascribe more *communal* characteristics to women—that is, ones associated with the welfare of other people—and more *agentic* characteristics to men—that is, those associated with assertiveness, control, and confidence (Croft, Schmader, & Block, 2015; Johnston & Diekman, 2015; Szabo, 2014). In short, women in the West are expected to be caring and men to be assertive and self-assured.

Men and women are often judged harshly when they step outside their gender roles (Croft et al., 2015; Lindsey & Christy, 2011). For example, in heterosexual relationships, women who leave their children with the male ex-spouse following a divorce are judged more harshly than men who leave their children with their female ex-spouse (Allen, Wright, & Pietenpol, 2017; Harman et al., 2016). Gender role also impacts attitudes at work. Studies find, for example, that when female managers were described to research participants as "successful," the individuals rated the woman as more hostile, selfish, quarrelsome, and subjective than successful male managers; however, in top-level positions, women are often viewed more favourably than men in similar positions (Eagly et al., 2019; Paustian-

Underdahl, Walker, & Woehr, 2014; Koenig et al., 2011). Nevertheless, as already discussed, since only a very small proportion of women reach the upper echelons in business, the general opportunities for advancement in the business world are limited for women (Meroño-Cerdán & López-Nicolás, 2017).

In 2015, 80 percent of Canadian women between 25 and 54 years of age participated in the paid labour workforce, compared to just under 91 percent of men (Statistics Canada, 2017). As well, women are 1.6 times more likely to earn a bachelor's degree than men (Moyser, 2017). Nevertheless, on average, women occupy lower-ranking positions and earn less income than men, with women employed full-time earning an average of 87 cents for every dollar earned on average by men, though this may be partially influenced by time in position (Canadian Human Rights Commission, 2010). Women constitute only 4.4 percent of the chief executive officers (CEOs) in Fortune 500 companies, and 5 percent of CEOs in Fortune 1000 companies (Catalyst, 2014).

Males are also constrained by gender role expectations (Lowrance, 2014; Levant, 2011). For example, males are often portrayed negatively if they step outside of accepted gender role occupations (Stanley, 2012); are often viewed as occupying a marginal role in the family context (Tsai & Shumow, 2011); and are less likely to seek counselling because of the associated stigma around male control and loss of control (Vogel et al., 2014; Wester et al., 2010). The imbalance in opportunity and expectation needs to be addressed for both genders.

Roles, Gender, and Social Skills

There is a popular belief in Western society that, on average, women are more skilled socially than men, more sensitive emotionally, more expressive, and more focused on social relationships (Hine, 2017; Bodenmann et al., 2015). For example, in a wide range of social psychology studies, it has been found that female participants tend to read non-verbal social cues more accurately than male participants (Hall, Gunnery, & Horgan, 2016), are more expressive with their faces and bodies during interactions and better able to read subtle emotional expressions (Lawrence, Campbell, & Skuse, 2015), and feel more empathy for the emotional experiences of others (Paulin et al., 2014). For their part, male participants tend to focus more narrowly on the tasks at hand in group activities than do female participants, emerge as leaders (as opposed to social facilitators) in group activities, and adopt more authoritarian and less participative styles when they take on leadership roles (Koenig & Eagly, 2014).

Although researchers have not fully sorted out the issue, one of the most common explanations for these differences is social roles (Steinberg & Diekman, 2016; Kmec, O'Connor, & Schieman, 2014). As we observed above, traditional Western gender roles ascribe more communal characteristics to women—including expectations that they should be friendly, unselfish, concerned about others, and emotionally expressive—and more agentic characteristics to men—including expectations that they will be assertive, independent, and controlling. According to social role theory, people are inclined to behave in ways that are consistent with the expectations tied to their roles (Huffman & Olson, 2017; Huffman et al., 2014). Moreover, over the course of their lives, as people enact their social roles, their skills in the assigned realm become sharper and their corresponding attitudes more deeply ingrained.

Roles and Situational Demands: The Stanford Prison Experiment

As we have just discussed, social roles affect not only how others think about us, but also how we think about ourselves and how we act toward others. In 1971, Philip Zimbardo and his colleagues at Stanford University studied the power of situations and roles in a study famously known as *The Stanford Prison Experiment* (Zimbardo, 2016, 2006a, 2006b, 2004, 1972; Haney, Banks, & Zimbardo, 1973). At the time, Zimbardo said that it was his intention to conduct the study to show the power of the situation as a "bookend" to the Milgram study, described later in this chapter (Drury et al., 2012). He wanted to see what would happen to good people put into bad situations and he wanted the situation to be in a controlled experimental setting. The basement of the university's psychology department was converted into a mock prison, and 24 male students—all paid volunteers—were randomly assigned to play the roles of either prisoners or guards for what was supposed to be a period of two weeks. The situation was contrived to include elements such as coercive rules, differences in power, anonymity for guards, as well as deindividuated roles for prisoners (Zimbardo, 2007).

The researchers wanted the experiment to mimic the experience of an actual prisoner or guard as closely as possible. "Guards" were therefore given batons, uniforms, and mirrored sunglasses, and were told that it was their responsibility to manage the prisoners and to run the prison. Guards worked eight-hour shifts with breaks. "Prisoners" were arrested by police as they went about their daily lives, were fingerprinted, blindfolded, and deloused, were given prison garb (smocks without under clothing), and were forced to wear small chains around their ankles. Their belongings were taken from them and they were referred to by assigned numbers instead of by name. They were in prison 24 hours a day. On the second day, the prisoners rebelled. The rebellion was quickly quelled and the guards retaliated by stripping the prisoners naked, removing their beds from their cells, and putting the ringleader in isolation. The guards began to taunt and harass the prisoners, imposing humiliating emotional and physical punishments on them (e.g., forcing them to act out (but not actually execute) sexual acts on one another, chaining their legs together, forcing them to perform endless pushups), and denying bathroom privileges and food to prisoners who were deemed "out of line" but giving special privileges to those who were obedient (e.g., allowing smoking breaks for those they liked) (see photo). The prisoners began to respond to the guards with blind obedience. Prisoners later reported that within days of beginning the simulation they felt as if they had lost their old identities. Zimbardo (1972) said that the prisoners developed "zombie like attitudes and postures, [and were] totally obedient to the escalating guard demands."

Philip G. Zimbardo, Inc.

The power of social role playing **In the famous Stanford Prison Experiment, most of the students who were assigned to play prison guards engaged in at least some abuses of power, and some guards were deemed sadistic, while those assigned to prisoner roles typically became passive, depressed, and disorganized.**

Zimbardo reported that he acted more like a warden, concerned more with the security issues facing the "prison" than by the plight of his participants. Christina Maslach, Zimbardo's girlfriend (and later his wife) forced Zimbardo to see just how extreme the situation had become. Zimbardo (2007) said, "Christina made evident . . . that human beings were suffering, not prisoners, not experimental subjects, not paid volunteers." So, after six days, the experiment was called off. The study demonstrated the situational power of roles and context in behaviour and not only explains but *predicts* real-life situations such as those at Abu Ghraib Prison in Iraq where high stress environments with little surveillance by those in charge result in extreme abuses of power. Zimbardo (2007) said it best: "The situation won. Humanity lost." Each of us has to prevent situations like these from winning; each of us has to learn this lesson to keep the power of situations (and the systems in which they reside) from overriding a person's moral centre and good sense.

The Stanford Prison Experiment raised many ethical concerns in the field of psychology, primarily because the participants experienced clear psychological pain—both the prisoners, who were abused psychologically, and the guards, who were confronted with the fact that they were capable of cruelty and even sadism (Tolich, 2014). In addition, it has been suggested that the study itself, aside from ethical considerations, was not well designed and contained problematic demand characteristics which are build in pressures for participants to behave in particular ways (Le Texier, 2019). As you read in Chapter 2, there are now ethical guidelines and review procedures that all researchers must follow when conducting studies—guidelines and procedures that would make it impossible for this same study to be conducted today.

Conformity

Conformity is the tendency to yield to real or imagined group pressure. Investigators have been studying conformity for more than 70 years. Early work on this phenomenon was done by social psychologist Theodore Newcomb (1943). In a classic study, Newcomb examined the political views of students at Bennington College as they progressed through school. Although Bennington College is known for the politically liberal leanings of many of its faculty members, during the Great Depression in the 1930s it was attended largely by children from conservative families. Newcomb found that as the students progressed through college, immersed in the Bennington culture, their political views grew more and more liberal. Moreover, these liberal views endured well into late adulthood, confirmed by interviews conducted 25 and 50 years later (Alwin, Cohen, & Newcomb, 1991; Newcomb et al., 1967). Laboratory studies tell a similar story, especially the classic work conducted by social psychologist Solomon Asch.

conformity the tendency to yield to social pressure.

The Asch Studies

Imagine that you agree to participate in a psychology experiment on "perceptual judgments." You and six other participants are seated around a table—you are seated second from the end—and the experimenter presents two cards to the group. The card on the left, Card A, displays a single vertical line, whereas the card on the right, Card B, displays three vertical lines of various lengths (see **Figure 13.6**). The experimenter asks each participant which of the three lines on Card B is equal in length to the line on Card A. When it is your turn, you immediately recognize that the second line on Card B matches the one on Card A. Thus, after the five participants seated ahead of you indicate that the second line on Card B is equal in length to the line on Card A, you do the same. Another set of cards is presented, and again everyone agrees. The straightforward task is moving along easily and comfortably.

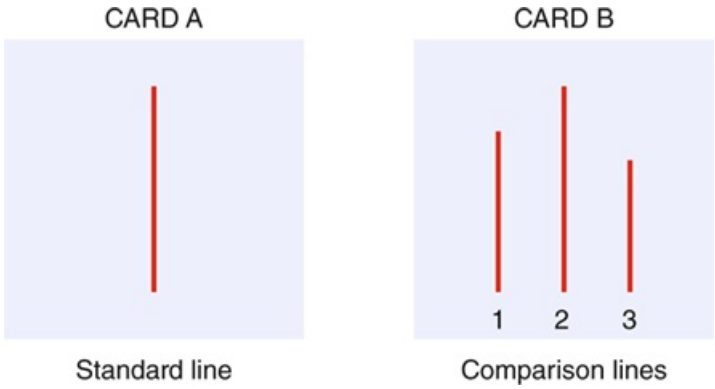

FIGURE 13.6 The perceptual judgment task in Asch's conformity study **Asch's participants were asked which line (1, 2, or 3) was the same length as the standard line. Despite the obvious and correct choice (line 2), when the confederates gave the wrong answer, almost 75 percent of the participants conformed and gave the wrong answer on at least one trial, too.**

Source: Adapted from Asch, S.E. (1955). Opinions and social pressure. ***Scientific***

American, 193(5), 31–35.

Then something odd happens. On the third round, you again readily note which line on Card B matches the line on Card A—it's pretty clear that it's line 3 this time—but you are shocked to hear that the first person called upon by the experimenter answers, "line 1." You think to yourself "he needs an eye exam," but then the second person responds the same as the first. You rub your eyes, blink, and squint, but still you see that it's line 3 that matches the length of the line on Card A. After the five people ahead of you have all selected line 1, it is your turn to respond. What will you say?

In fact, this classic study, conducted by social psychologist Solomon Asch (1955), was not about perceptual judgments at all, but rather was an investigation of conformity. In the study, the other "participants" were actually confederates, coached by the experimenter to give uniformly wrong answers on the third round and thereafter. Asch found that when the responses of the confederates were incorrect, almost 75 percent of the real participants conformed to the group norm and gave an incorrect response at least once.

Asch also varied the procedures in his experiment to reveal what group features might affect this "tyranny of the majority" (van den Bos et al., 2015), and others have followed with similar work. One key factor is group *unanimity*. The presence of even one dissenting group member dramatically reduces the likelihood that participants will conform to an incorrect group norm (Schmidt et al., 2016). The *size* of the group also affects its influence, as does the number of choices, with fewer choices leading to an increase in conformity (Curtis & Desforges, 2013). Groups with fewer than four members, for example, do not seem to bring about a powerful conformity effect (Asch, 1955; see **Figure 13.7**). Many laboratory studies on conformity have been conducted since Asch's pioneering undertaking (Bergquist & Nilsson, 2019; Beran et al., 2015; Kundu & Cummins, 2013). The findings of most such studies are similar to Asch's—they demonstrate the strong effects of social pressure.

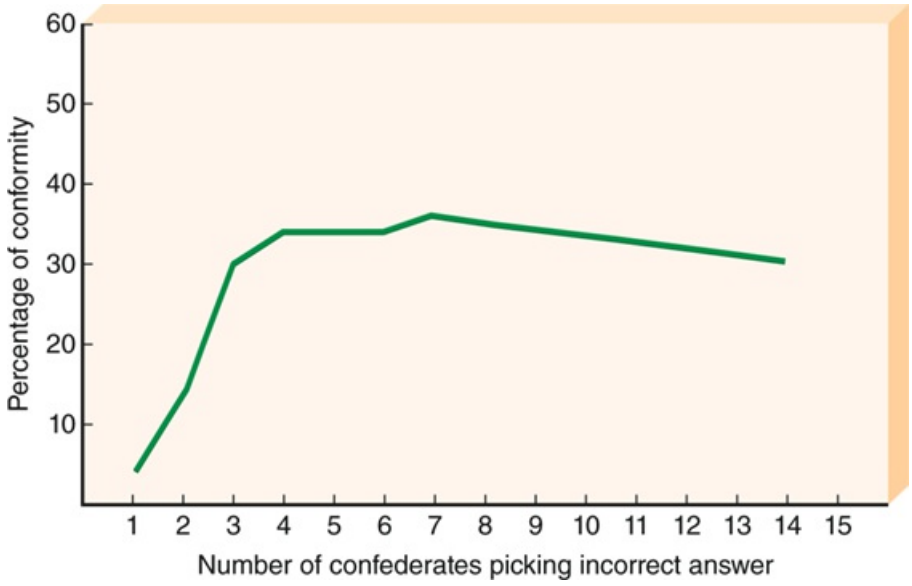

FIGURE 13.7 Group size and conformity **A key factor in conformity is group size. Asch found that the conformity effect is not strong when the group's size is less**

than four members (Asch, 1955).

Conformity and Culture

Conformity is viewed very differently in individualistic and collectivistic cultures (Patil, Tetlock, & Mellers, 2016). People in individualistic cultures often consider conformity to be a bad thing. Typically, members of this kind of culture want to stand out and be different—to have their own identity. In contrast, those in collectivistic cultures usually value fitting in with other people. They see virtue in conforming to social norms and view conformity as an indication of maturity, respect for others, and appropriate self-control (Hodges, 2017; Marcus & Le, 2013). In fact, the Korean word for conformity means inner strength and maturity.

When ordering food in a restaurant, people in North America—an individualistic society—order whatever they desire. They may say, for example, "I'll have a Caesar salad, but light on the croutons and with the dressing on the side." However, in Korea, a collectivistic culture, that kind of restaurant etiquette would be viewed with disfavour. It would be seen as an inability to get along with others and as insensitive to the needs of the waiter. Thus, as you might expect, whenever Asch-like studies are conducted in collectivistic cultures, the participants show even higher rates of conformity than do participants in the North American studies (Mori et al., 2014). On the other hand, Bhawuk (2017) found that at least some of this higher rate of conformity in collectivist cultures may be more apparent than real because individuals may remain silent or non-responsive at times to appear to conform rather take an oppositional position. Although collectivist cultures show a stronger tendency to comply, there was no significant difference on measures of internalization in this research. Another example of cultural limits to conformity can be seen in how many Canadian Indigenous parents, particularly in the prairies strongly resisted their children' attendance at residential schools (see Indigenous Experiences 13.2).

13.2 Indigenous Experiences

Parent Resistance

For over 150 years, more than 150,000 Indigenous children, many taken against their will and the will of their parents and communities, attended residential school. Some never returned. Residential school attendance was required by law. Parents who resisted were threatened with jail or fines. Nevertheless, while some parents complied, many did not. Some parents fought back, sending their children to friends and relatives in distant communities, hiding them, or campaigning for local community schools (Stromquist & Knickerbocker, 2015). Before the amendment to the Indian Act in 1920, making it mandatory for all Indigenous children to attend school, some parents simply refused to send their children to school. For example, in 1897, in an Indian Affairs statement, one official reported that a Saulteaux Cree chief would "not allow his children to be sent to school, says he would sooner see them dead, and on every chance he gets speaks against education and the Industrial Schools provided by the

Government" (Ray, Miller, & Tough, 2000, p. 194, as cited by Truth and Reconciliation Commission of Canada, 2012, p. 49).

Many other examples of historical resistance on the part of parents have been recorded. One example is of a father visiting his daughter at her school and seeing another child whose legs had been shackled. He insisted that the principal remove the chains and said, "These are children, not criminals, and I don't ever want to see cruelty like this again" (Truth and Reconciliation Commission of Canada, 2012, p. 50). Over decades, parents began to work together and withdrew their children as a group to protest cruel treatment or neglect, and eventually began to hire lawyers (Stromquist & Knickerbocker, 2015).

Among the best examples of parent resistance is an event that occurred in 1970 at the Blue Quills Residential School, near St. Paul, Alberta. Indigenous children from 12 surrounding reserves attended the Blue Quills school where the children's languages and cultures were systematically undermined, and abuse was common. Only four people working at the school were Indigenous; no teachers were Indigenous. One of these employees, a parent, as well as a former student from the school, Stanley Redcrow, had children at the school but he took them home nightly because he knew that was when the worst abuses occurred. In 1969, Redcrow and Alice Makoik, at the Department of Indian Affairs, discovered that Blue Quills school officials were planning to sell the school to the government for $1 and that the Indigenous students would subsequently be assimilated into the surrounding public schools. Redcrow, Makoik, and other parents and community members formed the Blue Quills Native Education Council and asked the Department of Indian Affairs for control of the school so they could teach Indigenous children about their own culture and history. They were not successful (CBC, 2017). So, in July 1970, Redcrow and other parents and activists staged a sit-in at the school, demanding control of their children's education. The protest began with 60 people but quickly grew to 300. The sit-in continued for 17 days and ended with 20 representatives meeting with Jean Chrétien, then Minister of Indian Affairs. The operation of the Blue Quills school was subsequently transferred to the Native Education Council (CBC, 2017; Bashford & Heinzerling, 1987).

Source: Canada:The Story of Us/CBC

Resistance at Blue Quills Residential School In 1970, Stanley Redcrow and

other parents staged a 17-day sit-in at Blue Quills Residential School demanding to be given control over the operation of the school and their children's educations (as depicted by actors in Canada: The Story of Us: CBC, 2017).

The school reopened in 1971 with Indigenous faculty, courses taught in Cree, and language revitalization lessons in Cree. The new school mandate was to have "children progress in the white man's education, while continuing to retain their dignity and self-respect as Indian people" (CBC, 2017). According to a CBC article looking back at the historical significance of the parent resistance, "The success of Blue Quills turned the tide of Indigenous education in Canada toward Indigenous self-determination" (CBC, 2017).

Critical Thinking Questions

What were some of the ways that the early resistance of Indigenous parents to residential school was viewed by the mainstream population?

What does considering the actions of resisting Indigenous parents in relation to their cultural heritage add to our understanding of their actions that was missing prior to the Blue Quills sit-in?

What might be involved in the education of Indigenous children if the goal to have "children progress in the white man's education, while continuing to retain their dignity and self-respect as Indian people" were to be achieved?

Obedience

In the Asch studies of conformity, there were no leaders in the groups—just peers. In addition, there were no consequences for incorrect responses. No fines were imposed, nobody was hurt, and nobody had to account for or defend their decisions. But what about situations in which people are working under an authority figure, or in which they must pay a price for making an incorrect decision? Classic work by researcher Stanley Milgram offers important, and unsettling, insights into situations of this kind. Milgram studied **obedience**, which occurs when people follow direct commands, usually given by an authority figure.

obedience the act of following direct commands, usually given by an authority figure.

Milgram's Experiment

Milgram's (1963) study is perhaps the most famous and controversial experiment in the history of psychology. Imagine that you have agreed to participate in this experiment. You arrive at the designated location and are met by a stern-looking man in a lab coat. The man introduces you to the mild-mannered "Mr. Wallace" and explains that the two of you are participating in a study of the effects of punishment on learning. One of you will be randomly assigned the role of "teacher," and the other the role of "learner." You are then

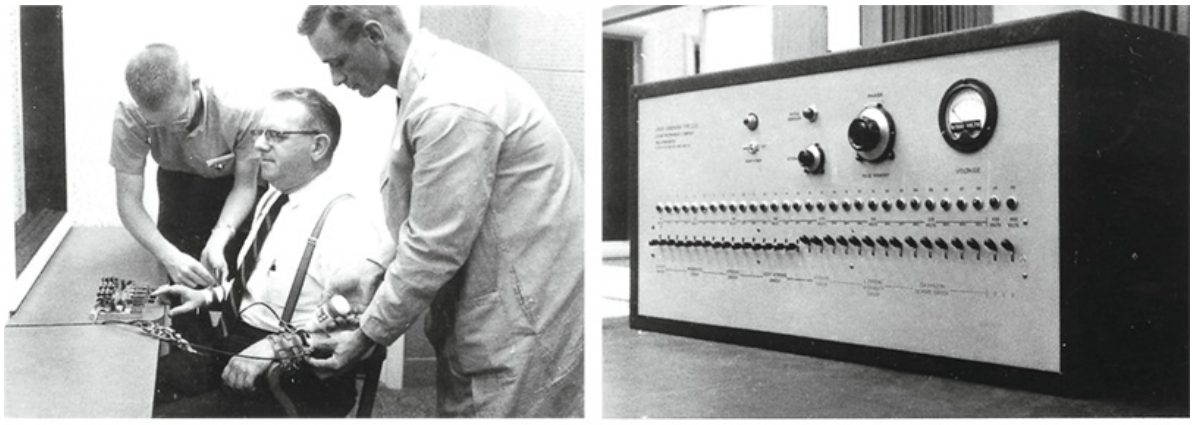
given the teacher role. Although you are not aware of it, the assignment of roles has not been random at all. Mr. Wallace is a collaborator in league with the experimenter who is really only interested in your behaviour.

The experimenter takes the two of you to an adjacent room, where Mr. Wallace is prepped for his role as learner. He is told to roll up his right shirt sleeve, and the investigator attaches an electrode to his wrist. His arm is strapped down "to prevent excessive movement," and electrode paste is applied "to prevent blisters or burns." You are informed that the electrode is connected to a shock generator in the other room (**Figure 13.8**).

The two of you are told that you (as the teacher) will recite a list of word pairs. After going through the entire list, you will recite only the first word of each pair, followed by four options. Mr. Wallace will indicate which option is the correct match for the first word by pulling one of four levers. If the response is incorrect, you will administer an electric shock. Mr. Wallace mumbles something about having a heart condition, but that comment is more or less ignored by the experimenter.

You are taken to another room, unable to see Mr. Wallace, and are seated in front of a metallic, box-shaped instrument, covered with knobs and switches and labelled "Shock Generator." You notice that each switch on the shock generator's control panel is identified by a voltage—ranging from 15 volts to 450 volts—and a label—ranging from "slight shock"(15 volts) to "danger: extreme shock" (375 volts) to "XXX" (450 volts). The experimenter explains that whenever you push down a switch, Mr. Wallace will receive the corresponding shock, and this shock will stop as soon as you push the switch back up.

You are to communicate with Mr. Wallace through a microphone intercom, as the rooms are "partially soundproof." When he responds by pulling one of the four levers, one of four lights on top of the shock generator will light up. You are to administer a shock to Mr. Wallace whenever he responds incorrectly. With each successive incorrect response, you are to move up one switch on the shock generator, administering what the labels suggest are increasingly powerful—and dangerous—shocks.



From the film Obedience ©1965 by Stanley Milgram. © Renewed 1993 by Alexandra Milgram. Distributed by Alexander Street Press.

FIGURE 13.8 Milgram's obedience experiment The photos above show the "teacher" helping the experimenter strap the "learner" into the shock apparatus and Milgram's shock generator. Most people believe that they would not administer shocks to a person crying out in protest, but Milgram's experiment

found otherwise.

After Mr. Wallace offers his first incorrect response, you flick the switch identified as "15 volts." The machine springs to life, with bright red lights flashing and an ominous buzzing noise filling the air. As Mr. Wallace continues to offer incorrect responses, you are instructed to administer increasingly powerful shocks. Through the wall, you can hear Mr. Wallace moan and say things, such as "Get me out of here!" Any time you express reluctance to go on, the experimenter confidently states "Please continue" or even, "You have no choice; you must go on." After a while, Mr. Wallace stops responding to your word prompts. The experimenter tells you to treat the failure to respond as an incorrect response and administer another shock (you're up to 450 volts, or "XXX," by now). Mr. Wallace lets out an agonized scream and yells, "Let me out of here! I have heart problems!" You hear and feel Mr. Wallace banging on the adjacent wall. Then he is completely silent. There are no further responses to your word prompts or to the shocks you administer.

As you are reading about this study, you are probably saying to yourself that you would have refused to go on with the experiment very early on. Most people who learn about this study have that reaction. Indeed, before the study became widely known, its procedures were described to psychologists, and they predicted that only 1 percent of participants would continue with the experiment all the way through 450 volts (Milgram, 1963). Astonishingly, Milgram found that 65 percent of the participants continued with the experiment all the way through the 450 volts label, and no participant stopped before the 300-volt mark (see **Figure 13.9**). As well, more recent replications of parts of the study (as the study as a whole would not receive ethics clearance today) show that things have not changed, and under similar circumstances participants would still behave as Milgram's initial participants behaved (Das, 2020; Blass, 2012).

The Milgram Controversy

It is no wonder that Milgram's study is one of psychology's most controversial. The study revealed something profoundly disturbing about human nature—namely, that we are inclined to obey authority, even if it means behaving in ways we would never predict we would behave. Milgram demonstrated that it is not just a cruel and sadistic fringe of the population that can inflict pain and suffering on innocent victims; two-thirds of the population might hurt others if ordered to do so by an authority figure. Milgram (1974) went on to explain the atrocities committed by Nazi Germany within the context of his remarkable findings, although a number of theorists have questioned the appropriateness of such a leap (Martin, 2016).

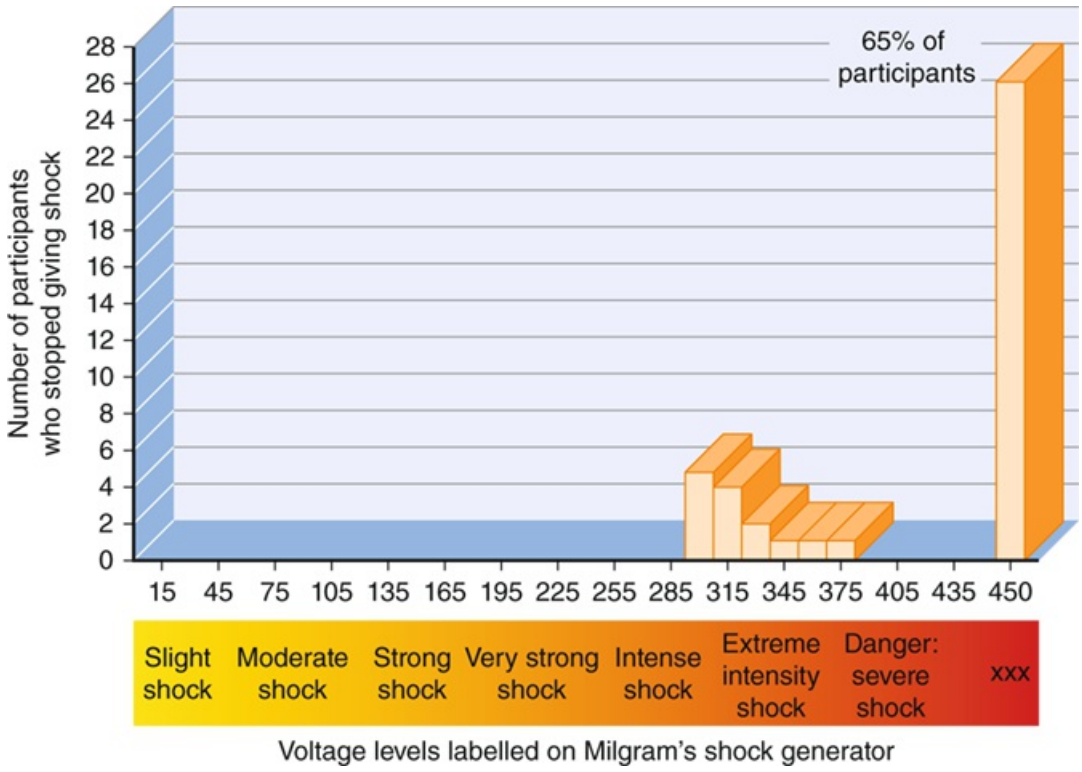


FIGURE 13.9 The results of Milgram's obedience experiment Milgram found that no participant stopped administering shocks before the 300-volt mark, and that the vast majority (65 percent) continued administering shocks to the highest level (Milgram, 1963).

Initially, many refused to believe that Milgram's findings provided an accurate representation of people's readiness to inflict suffering. Critics attacked the experiment on various grounds. Most notably, the participants in the original study were all male. Some speculated that women might be less inclined to obey commands to inflict pain on others. Additionally, a number pointed out that the study had been conducted at Yale University. Had it been carried out at a less prestigious locale, they argued, the participants might have been less likely to obey the experimenter's commands. Finally, many questioned the ethical implications of the research (Gibson, 2019; Griggs, 2017).

Follow-Up Studies

Milgram spent the years following the publication of his controversial findings conducting variations of the original experiment to further clarify the nature of obedience (Milgram, 1974). To the surprise of many people, he found that female participants were no more likely to defy an experimenter's commands than the male participants in the original experiment. Milgram also set up an alternative site for his experiment, the "Research Associates of Bridgeport"—supposedly a commercial organization that was not connected with Yale. In this variation, the percentage of people who kept administering shocks through 450 volts was somewhat lower than in the original experiment, but still considerable—around 50 percent, compared with the original 65 percent.

Further to that, a meta-analysis carried out by Haslam and colleagues (2014) to evaluate

factors impacting the original findings identified eight factors that predicted whether a given individual would go all the way to the 450 volt level of shock. Factors included the proximity of the experimenter to the person in the role as the teacher, as well as factors related to the connection between the teacher and the learner (e.g., three factors were related to the experimenter: how directive they were, how legitimate they were perceived to be, and how consistent they were). As well, if there was group pressure on the teacher to disobey, or proximity was indirect, the teacher's behaviour was also impacted. Finally, the behaviour of the teacher was influenced by proximity and amount of intimacy between the teacher and the learner and the distance between the experimenter and teacher.

Milgram's experiments and subsequent replications demonstrated just how ready people are to obey authority, but they also clarified that certain factors *reduce* people's willingness to obey (Hollander, 2015; Burger, 2014).

> If a confederate served as "co-teacher" with the research participant and refused to continue, over 90 percent of the real participants followed suit and disobeyed as well.
>
> The *salience* of a victim's suffering—its obviousness—affected participants' obedience. Participants in Milgram's studies were, for example, less likely to obey when they could see the look on Mr. Wallace's face with each successive shock.
>
> A participant's *proximity* to the victim affected obedience. When Milgram's participants were seated in the room with Mr. Wallace, only about 40 percent of them continued to obey through 450 volts. Still fewer (30 percent) were obedient in a condition that had them placing Mr. Wallace's hand on a shock plate to administer the shock.

Of course, there are many occasions in life where it can be quite useful, and even advantageous, to obey commands. During military manoeuvres, surgical procedures, theatre productions, and sporting competitions, for example, a lack of obedience may result in chaos or disaster. However, Milgram's study demonstrates the dark side of obedience. In a letter to another social psychologist, Milgram wrote, "Certainly, obedience serves numerous productive functions, and you may wonder why I focus on its destructive potential. Perhaps it is because this [the holocaust] has been the most striking and disturbing expression of obedience in our time" (Blass, 2004, p. 99).

It is important to note that Milgram's work was carried out in 1961 and 1962, prior to the advent of institutional ethics review boards. Yale University did not require informed consent from participants at that time. Instead, participants provided uninformed verbal consent and signed legal documents absolving Yale University of any liability. This type of research would not be allowed today (Howe, 2018; Haslam et al., 2014).

Before You Go On

(Answers to Before You Go On may be found online in the Course Resources.)

What Do You Know?

10. What are norms and what is their function in society?

11. What did Solomon Asch's experiments on conformity reveal?

12. What is the central difference between the concepts of conformity and obedience?

What Do You Think? • In both Asch's and Milgram's experiments, the presence of another person who would either go against the group or refuse to obey the authority figure made it more likely that the research participant would do so as well. How would you explain this phenomenon?

Social Relations

LEARNING OBJECTIVE 4

Review major concepts in the areas of group dynamics, helping behaviour, aggression, and interpersonal attraction.

Many social psychologists are interested in social relations. Some have studied *group dynamics*—how membership or participation in a group influences our thoughts and behaviours. Still others have attempted to determine when people choose to help others and when they will ignore others' needs. Other social psychologists have examined aggression and interpersonal attraction, trying to understand why people behave aggressively and how people come to like or love others in their social world.

Group Dynamics

A **group** is an organized, stable collection of individuals in which the members are aware of and influence one another and share a common identity. Group members are thus *interdependent*—that is, the behaviour of one group member affects the behaviour of the other members (see photo). Let's consider several topics related to groups and group dynamics: *group productivity*, *the social facilitation effect*, *social loafing*, *group polarization*, and *groupthink*.

group an organized, stable collection of individuals in which the members are aware of and influence one another and share a common identity.

Group dynamics **Membership or participation in a group influences our thoughts and behaviours.**

Group Productivity

One issue of interest to social psychologists is what makes groups productive. Not surprisingly, they have found that the optimal group size for productivity depends on the task at hand.

When a group is performing an *additive task*, its members must perform parallel actions. For example, to clear a property of snow after a storm, all members of a work crew must shovel snow. For such tasks, group productivity increases directly with group size.

In contrast, when a group is faced with a *conjunctive task*, the members are only as productive as the weakest member. If, for example, group members are hiking together up a mountain, they can travel only as fast as the slowest person in the group. In this situation, a greater number of group members does not necessarily yield better performance.

A *disjunctive task* requires a single solution. In such undertakings, the most competent person in the group is likely to provide the solution. Larger groups are typically more productive for disjunctive tasks, because a larger group is more likely to have a superstar member who can solve the problem at hand. Often large groups start by brainstorming for a solution to a task or problem. Asking group members to generate as many possible ideas or solutions as they can without being in any way critical of ideas proposed by others is a wonderful way to gather a broad range of possible solutions, and increases the likelihood that a useful solution will be found.

Divisible tasks involve the simultaneous performance of several different activities. When groups confront such tasks, no single person works on all phases of the undertaking; thus, the different strengths of group members complement one another. For divisible tasks, larger groups tend to be more productive, provided someone or a

part of the group manages or coordinates the activities of different parts of the group as they work on the components of the larger group task.

Video **PSYCHOLOGY@WORK**

Groups and Teams **This video looks at recent industrial/organizational psychology work on how teams function and how teams can be set up and supported in order to succeed. The video shows the value that corporate recruiters place on a person's ability to work in teams.**

Teams and groups are very important within organizations and workplaces these days. In fact, the ability to work well in a team setting is one of the most sought-after qualities in potential new hires (Jones, Baldi, Phillips, & Waikar, 2017). Industrial organizational psychologists study the factors that influence team engagement and performance. Check out the Psychology@Work video on Groups and Teams to find out more and also check out Practically Speaking 13.1.

Social Facilitation

In many instances, our performance is enhanced when we are in the presence of others. This is one of the oldest observations in social psychology. In the late 1890s, psychologist Norman Triplett noted that cyclists tend to go faster when in the presence of other cyclists than when alone—even when they are not in competition with one another (see photo). To test his hypothesis that the presence of others can enhance individual performance, Triplett (1898) conducted an experiment in which he had children wind a fishing reel either all alone or side-by-side with other children. Triplett found that children winding side-by-side worked substantially quicker than children winding by themselves. This phenomenon was later labelled **social facilitation**. Its study was expanded to include not just physical tasks, but also mental tasks, such as solving puzzles and doing math problems (Bond & Titus, 1983).

social facilitation an effect in which the presence of others enhances performance.

Stefano Rellandini/IOPP Pool/Getty Images

Improving each other's performance **Former Canadian Olympic cyclist Clara Hughes (front right) leads the pack during the women's cycling road race at the London 2012 Olympic Games. Research indicates that cyclists tend to go faster in the presence of other cyclists than when alone—the result of social facilitation.**

As social facilitation has been studied over the years, researchers have learned that people's performance in the presence of others is more complicated than Triplett first believed. Psychologist Robert Zajonc (1965) proposed that the presence of others elevates our arousal level, which in turn facilitates performance on simple, well-learned tasks, but interferes with performance on complicated tasks. In fact, research evidence supports this suggestion. For some tasks, and for some people, performing in the presence of others can impair—rather than enhance—performance (Monfardini et al., 2016; Yu & Wu, 2015). Zajonc's theory has received support from numerous studies and observations of both humans and animals (Rosenbloom & Perlman, 2016; Reynaud et al., 2015).

In recent years, theorists have focused less on the mere presence of others and more on individuals' *interpretations* of and *reactions* to the presence of others (Steinborn & Huestegge, 2020; Davidson & Keene, 2019; Varvatsoulias, 2016). If, for example, individuals do not like or trust other people in their group, their own contributions to a group project may suffer. In addition, if people believe that other group members are disregarding their ideas or efforts, their own performance in the group may decline (Baumeister, Ainsworth, & Vohs, 2015; Fiske, 2010).

13.1 Practically Speaking

Group Work to Teamwork

You have probably been in more than one or two courses that include a group project or group presentation as part of their required graded components. Did you enjoy the group work? If you said no, you are certainly not alone. Most students feel that group work puts them in a position where they are not in control of their course outcomes

(Allan, 2016). Before your next group project comes along, consider that when interviewing potential new employees, recruiters for organizations currently place the ability to work well in teams and related social (emotional intelligence) skills such as getting along well with others at or near the top of their wish lists—significantly higher than GPA and work experience (Jones, Baldi, Phillips, & Waikar, 2017). Very few colleges or universities offer courses or direct training in these sorts of soft skills (Gibert, Tozer, & Westoby, 2017). What to do?

Tom O'Neill is an industrial/organization psychologist at the University of Calgary who studies the links between group work and teamwork. He looks at ways that students can increase the short-term mark payoffs and longer-term employability payoffs through their participation in group course projects. His research provides some suggestions of things you can do to improve your group work experiences and marks and how you can add to your teamwork resumé along the way.

The first step is to pay attention to the different types of conflicts that arise during group work and teamwork projects (O'Neill et al., 2018a). Relationship conflicts occur when group members do not get along due to personality differences. The solution to these sorts of conflicts is to start by asking all group members to agree, up front, to be professional in their interactions with one another. Process conflicts arise when the group does not have a clear plan laid out for how the project will proceed. The solution is to work out a meeting schedule and obtain group agreement on project steps at the very beginning. Task conflicts involve disagreements about the details that are the core work of the project. To avoid task conflicts, O'Neill suggests using the four steps of a process called "SUIT." Group members are assigned group task components to gather information and work on and report back to the group. Each member then shares (the "S" in SUIT) what they gathered clearly with the group. The group listens closely and asks questions with the goal of understanding ("U") what each member presents and then works together to integrate ("I") the information gathered and ideas presented by each group member. Lastly, they make a team ("T") decision about how to proceed with their project (O'Neill et al., 2017).

Does this approach work? O'Neill found that groups that began by agreeing to put relationship conflicts aside, dealt with process conflicts up front, and focused on resolving task conflicts consistently got higher marks than did groups that spent more time struggling with relationship and process conflicts and did not get focused on task conflicts (O'Neill et al., 2018b).

How do you take your group work experiences with you so you can talk about your teamwork skills in job interviews? Once the group project is done, do a group or an individual (if the rest of the group is not interested) debriefing in which you review how the group managed the components of the SUIT process. As well, reflect on things that you or the group might have done differently that could have enhanced group performance (Eddy, Tannenbaum, & Mathieu, 2013; Lacerenza, Marlow, Tannenbaum, & Salas, 2018). The last step is to write your thoughts down because recruiters are not going to just ask if you work well in teams—they are going to want specific examples. If you keep your reflective debriefing notes, you will have a story or two to tell that will verify your teamwork and social skills. Good luck!

Social loafing **Social loafers leave the work of a collective task to others in the group.**

Social Loafing

Groups are often formed in hopes that an interconnected body of people can energize and motivate every individual member. However, these hopes are not always realized. When working in a group, how many times have you noticed that one or two of the group

members are not pulling their weight? **Social loafing**—also known as *free riding*—refers to the phenomenon in which people exert less effort on a collective task than they would on a comparable individual task (Byun, Lee, Karau, & Dai, 2020; Czyż et al., 2016; Simms & Nichols, 2014). (See photo.)

> **social loafing** a phenomenon in which people exert less effort on a collective task than they would on a comparable individual task; also known as free riding.

Social loafing seems to rear its ugly head most often in large groups (Cummings et al., 2013). It is most likely to occur when certain group members lack motivation to contribute, feel isolated from the group, calculate the cost of contributing as too high, or view their own contributions as unnecessary (Meyer, Schermuly, & Kauffeld, 2016). Research suggests that people from Western cultures are more inclined to display social loafing than people from Eastern cultures, and men are more likely to do so than women (Simms & Nichols, 2014).

Fortunately, social loafing can be minimized. When, for example, groups are highly *cohesive*—when group members all desire and value membership in the group—the social loafing phenomenon all but disappears (Meyer et al., 2016; Schippers, 2014). Additionally, social loafing is reduced when group members are each explicitly reminded of their uniqueness and importance (Tsay et al., 2014), when they are given specific and challenging goals (Schippers, 2014), when the output of each member is publicly identified, and when the members are given clear norms and comparison standards for their work (De Backer et al., 2015; Takeda & Homberg, 2014). Finally, alertness tends to decrease social loafing, whereas fatigue tends to increase it.

Group Polarization

Have you ever begun talking about one of your favourite bands with a group of friends with similar musical tastes, and found yourself liking the band even more by the end of the conversation? When an initial tendency of individual group members is intensified following group discussion, **group polarization** occurs (Sieber & Ziegler, 2019; Evans, 2017; Roux & Sobel, 2015; Isenberg, 1986). This phenomenon is not simply an example of conformity. With group polarization, the attitudes and inclinations of the individual group members are already in place, and they become more intense and more extreme as a result of the group interaction (Effron & Knowles, 2015).

> **group polarization** the intensification of an initial tendency of individual group members brought about by group discussion.

Group polarization has been studied most often with regard to racial and ethnic bias and social and political attitudes (Effron & Knowles, 2015; Iyengar & Westwood, 2015). When, for example, researchers have placed individuals with highly prejudiced attitudes in a group to discuss racial issues, the attitudes of the individuals tend to become still more prejudiced (Willis, 2017; Myers & Bishop, 1970). In similar work, it has been found that the attitudes of women with moderate leanings toward feminism become more strongly feminist following group discussions (Kolers, 2016).

Groupthink

Groups often come together to solve specific problems and make decisions. We noted earlier that group cohesiveness can prevent social loafing—but sometimes, groups can become *too* cohesive and single-minded, and the group's decision making can lead to disaster. A classic example occurred in the early 1960s, when the Kennedy administration in the United States government was determined to overthrow Fidel Castro's Communist government in Cuba. The U.S. government had trained a small group of Cuban exiles as part of a military operation to overthrow Castro. Proponents of the plan predicted that once this small militia touched down in Cuba at the Bay of Pigs, the Cuban citizens would rise up and join them. Instead, the operation collapsed, with no support from the Cuban people and no further help from the U.S. government. As a result of the failed invasion, anti-American sentiment around the globe increased, as did Castro's influence in Latin America, and Cuba's ties with the Soviet Union were strengthened. There is evidence that no one within Kennedy's inner circle raised any concerns about the viability of the plan in part because they were focused on finding a solution that would please the president. There was a strong sense of shared certainty that the Cubans would rise up and support the small invasion force (Janis, 1972).

NASA/Getty Images

A consequence of groupthink? In 2003, the space shuttle Columbia disintegrated during re-entry over Texas, killing all seven crew members. Just two days before the disaster, a NASA engineer had warned his supervisors of possible catastrophes on re-entry, but his message was not forwarded up the chain of command. How might groupthink have been involved in this mishandling of the warning?

Psychologist Irving Janis (1972), after examining the flawed decision-making process that went into the Bay of Pigs invasion, attributed the fiasco to what he termed **groupthink**. He defined groupthink as a form of faulty group decision making that relies on overfocused and biased thinking and occurs when group members reach premature conclusions in a

misguided effort to achieve unanimity (see photo). The goal of achieving a consensus among all group members overrides the need to realistically appraise alternative courses of action. Clearly, groupthink can have undesired consequences (Mintz & Wayne, 2016, 2014; Sunstein & Hastie, 2015). The botching of the Bay of Pigs incident increased tension between Russia and the United States and was a factor in precipitating the Cuban Missile Crisis.

> **groupthink** a form of faulty group decision making that occurs when group members strive for unanimity, and this goal overrides their motivation to realistically appraise alternative courses of action.

Janis identified a number of conditions that set the stage for groupthink: (1) strong similarity in group members' backgrounds and ideologies; (2) high group cohesiveness; (3) high perceived threat; (4) elevated stress; (5) insulation from outside influence; and (6) a directive, often charismatic, leader. As a result of these conditions, group members experience an illusion of invulnerability and have an unquestioned belief in the group's inherent morality. Typically, group members exert direct pressure against any member who expresses strong disagreement, and members protect the group from information that might shatter the shared conviction that their decisions are effective and moral (Janis, 1982). See Psychology Around Us 13.2 to read an example of the result of a disastrous decision-making effort at the National Aeronautics and Space Administration (NASA).

Having identified the phenomenon of groupthink, Janis went on to propose measures that a group can take to safeguard against it. First, the leader of the group should encourage members to air objections and doubts, and should accept criticisms of the group's judgments. Additionally, various group members should be assigned the role of "devil's advocate," arguing against the group's favoured position. Finally, outside experts should be invited to group meetings and encouraged to challenge the group's core views and decisions.

U.S. President Kennedy learned from his mistakes with the Bay of Pigs invasion. When faced with evidence of Soviet ballistic missile sites in Cuba in 1962, Kennedy used a much different approach to decision making, adhering to many of the safeguarding measures subsequently suggested by Janis. As the world teetered on the precipice of nuclear war during the Cuban Missile Crisis, the president established an Executive Committee of the National Security Council headed by the vice-president and the attorney general to determine a course of action. Kennedy gave committee members time to gather information and explore options. He then recused himself from their meetings so as not to inadvertently direct the recommendations, but without their knowledge, he tape recorded their meetings for review purposes. He instructed the attorney general to act as "devil's advocate," forcing the members to discuss and debate the merits of different strategies for the group. After 13 days, an atomic confrontation was narrowly averted. Why is such an old event covered in such detail here? At the time of writing, North Korea's leader and the then-president of the United States could have been facing a similar crisis.

13.2 Psychology Around Us

Space Disasters and Groupthink

"On the morning of January 28, 1986, the space shuttle Challenger blasted off from the Kennedy Space Center in Florida. Seventy-three seconds after lift-off, the Challenger exploded, killing all seven astronauts on board . . . Following the explosion . . . information came to light about the faulty decision-making processes . . . that [had] led to the decision to launch. Some engineers had expressed concerns about the design of the O-ring seal in the solid-fuel rocket, which could allow hot gases to leak through the joint and thereby spark an explosion. However . . . these concerns were ignored . . .

"Unfortunately little was learned from this tragic accident because many of these same errors contributed to the loss of the Columbia space shuttle, and its seven astronauts, on February 1, 2003 [the shuttle was trying to return to earth after a 16-day mission in space]. Research now shows that prior to the Columbia disaster, some NASA engineers had grave concern about the shuttle's ability to return to earth following some tile damage it [had] experienced on lift-off. On January 28, just days before the Columbia tragedy, a landing gear specialist at NASA sent an email expressing his concerns about the tile damage . . . However, high-level NASA administrators viewed the damage to the shuttle as minor—not a serious threat—and refused to respond . . ." (Sanderson, 2010)

Research conducted since Janis first proposed his theory suggests that groupthink is a complicated phenomenon—probably more complicated than Janis initially realized. The conditions that he believed set the stage for groupthink do not always result in unwarranted unanimity (Sethi, 2017; Houghton, 2015). Nor do his proposed safeguards always prevent groupthink. At the same time, research and observations clearly indicate that the phenomenon of groupthink is widespread. Not only does it often affect decision making in important policy-setting groups, as Janis recognized, but it also influences decision making in mundane and temporary groups and groups working on trivial matters (Stingl & Geraldi, 2017; Frey, Schulz-Hardt, & Stahlberg, 2013).

Helping Behaviour

When people are in need, many people offer help as an expression of **altruism** (concern for or acting to help others without any expectation of compensation or reciprocation) or of another social motive. In 2016, while the displaced and anxious evacuees from Fort McMurray, Alberta, watched in horror as their city burned due to a raging wildfire, offers of accommodation, assistance, and aid poured in from across Canada. Residents of Fort McMurray, while devastated by their losses, felt supported and cared for by their fellow Canadians. Other examples of altruism that have inspired others include Terry Fox's run for cancer, Rick Hansen's Man in Motion world tour in support of spinal cord research and the HumboldtStrong response to help families affected by the tragic loss of 16 members of the Humboldt Broncos hockey team in a bus collision in Saskatchewan in April 2018. All of these selfless accomplishments have led to many more altruistic activities, with many people across Canada and around the world participating in Terry Fox runs every year.

altruism self-sacrificing behaviour carried out for the benefit of others.

Why Do We Help?

Altruism refers to self-sacrificing behaviour carried out for the benefit of others. To be altruistic, behaviour must be motivated by concern for persons in need, without concern for oneself (Feigin, Owens, & Goodyear-Smith, 2014; Moorlock, Ives, & Draper, 2014). Thus, engaging in self-sacrificing behaviour to avoid a sense of guilt or donating to charity for tax purposes would not be considered altruistic behaviour. Such acts, which are motivated by a desire to reduce one's own personal distress or to receive rewards, are sometimes called *egoistic helping behaviours* (Siem & Stürmer, 2018; Dickert, Västfjäll, & Slovic, 2015).

Albert Gea/Reuters

Responding to tragedy **Almost immediately after a series of terrorist bombs ripped through passenger trains in Madrid, Spain in 2004, killing 191 people and injuring 1800 others, Spanish citizens such as these began lining up to donate blood to the victims. Altruism? Possibly. But social psychologists point out that egoistic motives may also be at work during the early reactions to tragedies of this kind.**

When we engage in helping behaviour, our motives can be entirely altruistic, entirely egoistic, or some combination of the two. Surveys have revealed that in the *immediate* aftermath of the 9/11 terrorist attacks, actions such as giving blood, money, and goods and offering prayers were associated with both altruistic and egoistic motives (Chung et al., 2016). (See photo.) People's motivations for giving ranged from wanting to ease the suffering of others, to hoping to reduce their own attack-induced distress and seeking to reassure themselves that other people would help them if they were in need. In contrast, *sustained* giving after the attacks—that is, giving after one or more years—may have been more consistently associated with altruistic motives.

Research further indicates that certain factors increase the likelihood of altruistic behaviour. When people empathize and identify with the individuals in need (Atabaeva, 2019; Lemmon & Wayne, 2015), as well as when they are in close relationships (Mikulincer & Shaver, 2017; Xue, 2013), they are more likely to behave altruistically. Similarly, people tend to display more altruism when they take the perspective of victims (van Loon et al., 2018; Feigin et al., 2014). Not surprisingly, then, people who are generally trusting and outward-looking and who form secure attachments in their relationships are most likely to

perform altruistic behaviours (Paulus et al., 2016; Lozada, D'Adamo, & Carro, 2014). As you can see, it is often quite difficult to identify and understand the specific motives that drive people's helping behaviour, and especially to determine if their behaviour can be seen to be truly selfless and thus truly altruistic. Questions about the existence and nature of altruism have been taken up as central interests by psychologists working in the area of positive psychology (Batson, Lishner, & Stocks, 2015).

Positive psychology is the scientific study of the strengths and virtues that help human beings, as individuals and families, to thrive, and communities to flourish (Krumrei-Mancuso, 2017). Researchers in this field argue that other approaches to psychology focus on dysfunction and abnormal behaviour and, while they acknowledge the importance of remedying problems, they also argue that focusing on strength is as important as focusing on weakness. They believe that focusing on well-being is as important as focusing on suffering. Martin Seligman, widely regarded as the father of positive psychology, believed that the time was right for a scientifically-informed psychology about positive human functioning. Positive psychologists study empathy (Lasota, Tomaszek, & Bosacki, 2020; Prot et al., 2014), altruism (Valsala & Menon, 2019; Batson, 2014), gratitude (Emmons, Froh, & Rose, 2019; Tsang et al., 2014), resilience (Hogan, 2020; Luthar, Lyman, & Crossman, 2014), mindfulness (Lomas et al., 2019; Kashdan & Ciarrochi, 2013), and happiness (Eckhaus & Sheaffer, 2019; Argyle, 2013), as well as other areas they claim make life more worth living (Compton & Hoffman, 2019). A good example of Positive Psychology research involves how giving to others or prosocial giving makes donors feel (see Positive Psychology 13.2).

Bystander Effect (or Bystander Apathy)

Imagine you are in a life-threatening situation and desperately need the help of others. If you could choose, would you prefer that one or two people were nearby or that a large number of people were present? If you are like most people, you probably would prefer the larger number. After all, that would mean more potential helpers. In fact, however, this may be the more dangerous choice. It turns out that, in many circumstances, the more people present in a situation where help is required, the less likely it is that any one person will give that help (Doramajian & Bukowski, 2015; Hortensius & de Gelder, 2014; van Bommel et al., 2014).

13.2 Psychology Around Us | Positive Psychology

Prosocial Spending and Happiness

Social psychology researchers often study the effect that money has on happiness. Most people are surprised to find out that even the perception of wealth can impair a person's ability to appreciate simple daily experiences, such as enjoying a smooth, rich, dark (or milk if that's your preference) piece of chocolate (Quoidbac, Dunn, Petrides, & Mikolajczak, 2010). This decreased ability of participants to truly savour the effects of wealth on enjoying an everyday experience led Elizabeth Dunn, at the University of British Columbia, to start studying the effects of prosocial spending on happiness. Research from her laboratory, published in the prestigious scientific journal *Science*, has shown that people who spend money on others report increased happiness,

especially when that money is spent on people you feel strongly connected to socially (Aknin, Sandstrom, Dunn, & Norton, 2011; Dunn, Aknin, & Norton, 2008). This effect of prosocial spending on happiness can be observed around the world, and has even been reported in toddlers (Aknin et al., 2013; Dunn, Aknin, & Norton, 2014). The effect of prosocial spending appears to be strongest in individuals who already feel concern for others outside of themselves (Hill & Howell, 2014). Whether this increase in happiness due to prosocial spending lasts for more than a few days is currently debated (Falk & Graeber, 2020). However, the general consensus seems to be that prosocial spending does give, at least in the short term, a happiness boost.

Frederic Stevens/Getty Images

Helping our world one disease at a time **Two individuals who are well-known for their prosocial spending are Bill Gates, a co-founder of Microsoft, and his wife Melinda. The Bill and Melinda Gates Foundation is known for its funding of initiatives that support gender equality, access to contraceptives, climate change action, and the eradication of global diseases such as AIDS. They are pictured receiving the prestigious Légion d'Honneur medal in Paris for their charity work around the world. Despite the possible effects of this level of prosocial spending on happiness, the Gates announced in 2021 that they were divorcing suggesting that the relationship between prosocial spending and happiness is complex.**

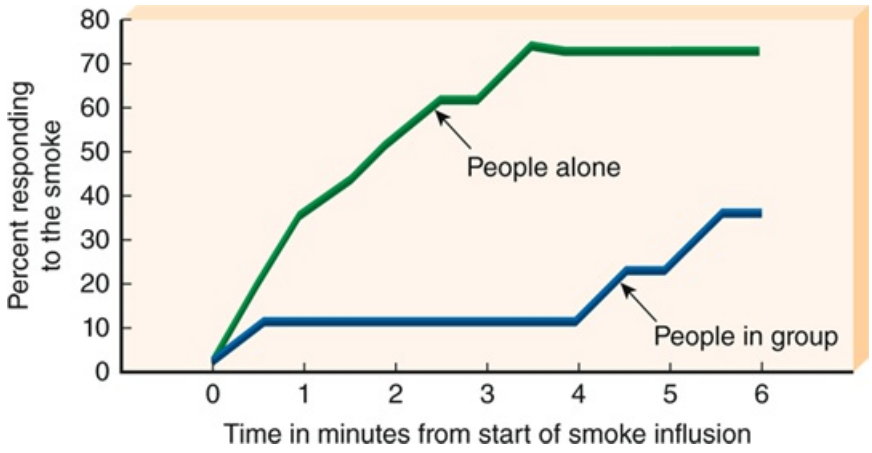

FIGURE 13.10 Bystander intervention People are more likely to intervene to help when they are alone than in a group. In the presence of others, people feel less compelled to act, a phenomenon called the *bystander effect* (Darley & Latané, 1968).

Source: Adapted from Myers, D. G. (2002). *Social psychology* (7th ed.). New York: McGraw Hill, Figures 3-2 and 12-4; based on Darley, J. M., & Latane, B. (1968). Bystander intervention in emergencies: Diffusion of responsibility. *Journal of Personality and Social Psychology, 8*, 377–383.

Consider the following story: on March 13, 1961, a woman named Kitty Genovese was purportedly stabbed to death over the course of three separate attacks spread over 30 minutes in the New York borough of Queens, while at least 38 neighbours and other onlookers failed to intervene. This rendition of a famous murder was followed by a public outcry demanding an explanation for the lack of intervention by others, including a *New York Times* article with the headline: "Thirty-Eight Who Saw Murder Didn't Call the Police" (Gansberg, 1964). Initially, many observers concluded that these 38 bystanders must have had a host of personality flaws that prevented them from helping. But were they really callous and uncaring?

Social psychologists John Darley and Bibb Latané (1968) were less interested in the personality traits of these onlookers than with features of the situation that might have kept them from providing help. In a series of studies examining the impact of the presence of others on helping behaviour, Darley and Latané repeatedly demonstrated that we are, in fact, more likely to intervene when we are *alone* than when others are also present. In one of their studies, for example, participants found themselves in a situation where they smelled smoke (faked by the experimenters) while either alone or in the presence of others. When other people were present in the room, fewer than 40 percent of the participants got up to report the smoke; in contrast, 75 percent of the participants in the study reported smelling smoke when they were alone in the room (see **Figure 13.10**) (Latané & Darley, 1968). In another experiment by the two researchers, participants were placed in a situation in which they overheard a person (actually an actor) in another room having a seizure. The more people the participants believed could also hear the individual having the seizure, the less quickly they acted to help (Darley & Latané, 1968).

This phenomenon has been termed *bystander effect*. If your car is broken down in the rain

at the side of the road and no one is stopping to help, you may be experiencing firsthand the bystander effect. Researchers in addition to Darley and Latané (1968) have observed group bystander effects of this kind under a wide variety of conditions, with none, one, or more bystanders, including situations in which a person witnesses someone stealing money from another (both with and without a security camera) (van Bommel et al., 2014), graffiti was written on an elevator wall (Chekroun & Brauer, 2002), or a perpetrator is determined to be either dangerous or non-dangerous (Fischer et al., 2011).

Ann Cutting/Getty Images

Diffusion of responsibility **People are less likely to stop and help an apparently lost child if they are part of a large crowd than if they are walking alone on a street. Why? When many others are present, we are not as likely to feel the full burden of responsibility.**

What must occur for bystanders to intervene on someone else's behalf? Researchers believe that several steps are involved (Levine, Philpot, & Kovalenko, 2020; Jouriles et al., 2016; Nickerson et al., 2014; Latané & Darley, 1970). Bystanders must: (1) notice the event; (2) interpret the event as an emergency; (3) feel personal responsibility for acting; (4) consider what form of assistance is needed; and (5) implement action (Brewster & Tucker, 2016; Jenkins & Nickerson, 2016).

Some theorists have focused on the third step, *feeling a sense of personal responsibility*, as the key to bystander apathy (Ashburn-Nardo, Lindsey, Morris, & Goodwin, 2019; Thomas et al., 2016). They suggest that the presence of a large number of people in an emergency situation creates a *diffusion of responsibility* (Freeman et al., 1975), an effect observed in fMRI studies (Hortensius & de Gelder, 2014). When others are present, we feel that we do not bear the full burden of responsibility, and thus we feel less compelled to act. We may also assume that someone else must be taking action (see photo).

Finally, research is starting into issues of bystander reactions to violence within virtual realities, such as cyberbullying over social networks, as well as over shared and online video games and worlds. Early work suggests that similar forces are at work shaping the

behaviours of virtual bystanders as they do for bystanders in the "real" world (Machackova, 2020; Machackova & Pfetsch, 2016).

Researchers Cook (2014) and Lurigio (2015) have reviewed the evidence from the Kitty Genovese murder and both argue that aspects of the case have assumed the stature of an urban legend. They argue there is no evidence that all of the details of the Kitty Genovese murder are accurate. In particular, the researchers argue that there was misinterpretation on several levels. First, there is no evidence that 38 eyewitnesses were ever involved, with only five witnesses admitting to hearing or seeing anything. As well, there is no evidence that one witness saw the entire sequence of events. Indeed, there is no evidence that anyone saw the second attack at all (or a third attack—there were never three attacks) as the final attack occurred in an inside stairwell. As well, there is evidence that the police *were* called and that at least one of the eyewitnesses discouraged the first attack by threatening the assailant from the window of his apartment, chasing the assailant away following the first attack. It has also been suggested that the police may have supported the advancement of the bystander effect argument to cover their own inactions (Kassin, 2017). This is not to argue that the eyewitnesses could not have been more proactive and might have handled things differently and more effectively. This does, however, suggest that some aspects of the story are not supported by the evidence. Why is this important?

Although the bystander body of work is robust and replicable, we continue to view groups as detrimental to social functioning, largely based on this story of the 38 witnesses. There is, however, evidence to suggest that groups can serve a strong prosocial function and facilitate helping (Cronin & Hopper, 2017; Levine & Manning, 2013).

The ubiquity of smart phones today adds another variable to bystander behaviour. Human behaviour is rarely, if ever, clear-cut or black and white. It does not typically conveniently fall into categorical labels. We can try to apply what we have learned in this chapter about stereotypes, racism, and the bystander effect to a Canadian situation, that of the arrest of Chief Allan Adam of the Chipewyan First Nations.

Chief Adam was violently arrested by RCMP on March 10, 2020, outside of a casino in Fort McMurray, Alberta, because of an expired licence plate (Fife, 2020). The full video recording can be found at www.theglobeandmail.com/politics/article-Indigenous-chief-says-rcmp-beat-him-up-and-manhandled-his-wife-over/. In this video, both Chief Adam and his wife can be seen getting assaulted, with no apparent provocation. Chief Adam was pinned to the ground and his head was pounded against the asphalt. Toward the end of the video, bystanders can be seen stopping and taking videos with their devices. Some went to speak with Chief Adam's wife after he had been beaten and removed before she was removed and handcuffed, although they backed away when the numerous RCMP officers moved in line formation toward her, as she was sitting in the vehicle. So bystanders "intervened," but they did not interfere. Why? What does this say about the relations between the people in this video? What does this suggest about the standing First Nations peoples feel they have in our society, or with our law enforcement agencies? Consideration of the cases of Chantel Moore (Meissner, 2020) and Regis Korchinski-Packet (Gillis & Moon, 2020) might add to your reflections.

If you read the articles about Chief Adam, consider also the earlier references in this chapter on media bias as well as the commentary in Thurston & Schill (2015), referred to in

the section on Stereotypes and Prejudice, in particular when considering the perspective presented in the Canadian Press article (2020, June 24) stating the reasons for dropping the charges against Chief Adam. Given what you see in the video, is the presented perspective valid? What impact could this perspective have on public perception of First Nations peoples?

Aggression

In social psychological terms, **aggression** describes a broad category of behaviours, including physical and verbal attacks, intended to do harm to another. Aggression appears to have at least some biological underpinnings. Twin studies indicate that identical twins are more likely to share the trait of violent temper than fraternal twins, suggesting a genetic component (Tremblay, 2015). High levels of the hormone testosterone have been linked with higher levels of aggression, as have low levels of the neurotransmitter serotonin. Indeed, the people most likely to be involved with violent crime are muscular young men with below-average intelligence, high levels of testosterone, and low levels of serotonin (Ellis & Hoskin, 2015; Weierstall et al., 2014).

aggression a broad range of behaviours intended to harm others.

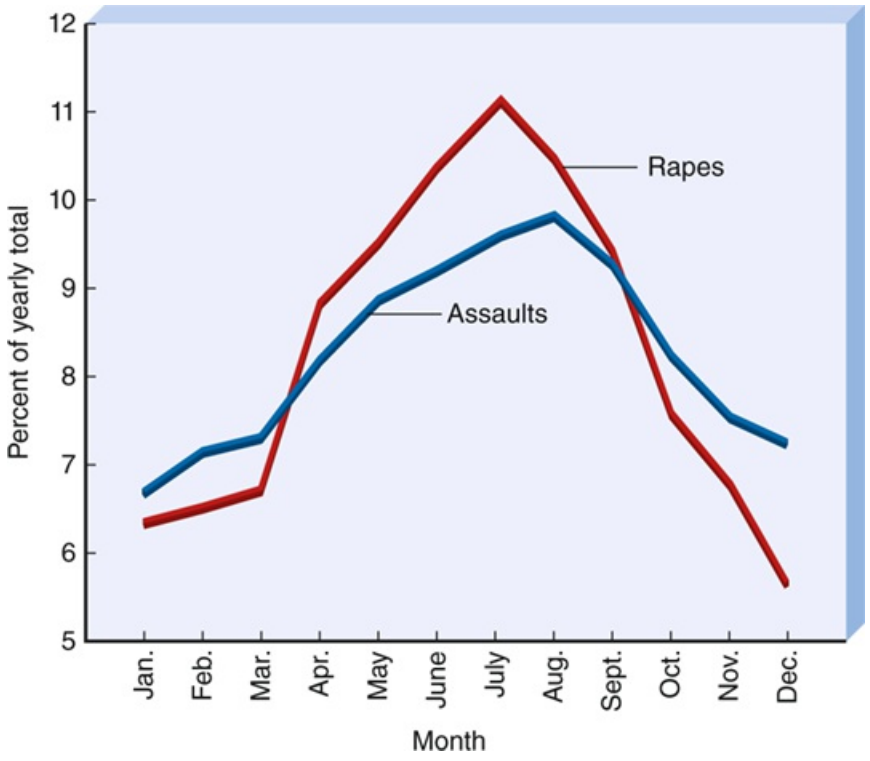

FIGURE 13.11 Aggression by time of year **Studies of data in North America and Europe over the last hundred years show that aggression is highest in the hottest months of the year (Anderson, 1989).**

That said, under the right circumstances, we are all capable of aggressive acts. One major hypothesis explaining aggression in humans—the *frustration-aggression hypothesis*—holds

that we become aggressive in response to frustration (Dollard et al., 1939). Any emotional stressor that impedes our progress or prevents achievement of some goal elicits frustration. Aggression, then, might be a cue to push harder to achieve that goal.

The frustration-aggression hypothesis was later expanded to include the notion that any unpleasant event, ranging from experiencing a bad odour or an annoying sound to hearing bad news, leads to activation of the sympathetic nervous system. As you will see in Chapter 14, activation of the sympathetic nervous system is associated with both anger and fear and with the fight-or-flight response. This theory suggests that if you have translated this activation to aggressive behaviour in the past, and the outcome has had a desired effect, you will continue to engage in that aggressive behaviour (Falkner & Lin, 2014).

Other factors influencing aggression probably result from both biology and environment (**Figure 13.11**). For example, as we have observed previously, men tend to be more aggressive than women—at least in some respects. Women are more likely to engage in acts of *relational aggression*, such as snubbing, gossiping, and otherwise excluding others as a means of venting frustration or anger (Andrews, Martin, & Gallagher, 2016; Ferguson, Zimmer-Gembeck, & Duffy, 2016). (See photo.) However, men are more likely to engage in *direct aggression*, which includes direct physical and verbal abuse. In fact, the vast majority of violent offenders are male (Stephenson, Woodhams, & Cooke, 2014). Because this gender disparity shows up very early in childhood, it may be at least partially attributable to biological gender differences. However, it is probably also affected by social norms within our society, where men are more permitted than women to express anger and act aggressively.

Digital Vision/Getty Images

Relational aggression **On average, women are more likely than men to express their anger with relational aggression (for example, ignoring the person who has angered them).**

Alcohol has also been found to increase aggressive behaviour for both biological and psychological reasons (Crane et al., 2017). The effects of the drug may reduce inhibitions and so make people more likely to engage in violence or verbal abuse. However, people have been shown to become more aggressive even if they only think that they have had alcohol to drink, suggesting that they are responding to social expectations about how

people act when they have been drinking (Berke, Leone, Parrott, & Gallagher, 2020; Johnson, 2014; Ostrowsky, 2014).

Interpersonal Attraction

Why are we attracted to some people and not others? What's the difference between liking someone and loving someone? These are questions central to the study of interpersonal attraction. Interpersonal attraction operates at three levels: *cognitively*, we think certain things about the other person; *affectively*, we experience particular feelings toward the person; and *behaviourally*, we act in certain ways toward the person (Montoya & Horton, 2020; Huston, 2013).

Liking

Liking refers to fondness and affection for another person. Research has revealed five key factors that lead to liking someone.

Similarity—The more similar to us we perceive someone to be, the more likely we are to develop a fondness for that person. In addition, the more similar people are, the likelier it is that their fondness for one another will last a long time (Hampton, Fisher Boyd, & Sprecher, 2020; Kaptein, Nass, & Markopoulos, 2014).

Proximity—We tend to like people whom we encounter frequently more than those we do not encounter often, and we tend to like familiar people more than unfamiliar people (Shin et al., 2019; Sommer & Bernieri, 2015). How many people with whom you have shared two or three classes have become friends?

Self-disclosure—We tend to initially like people who disclose personal information to us, and we tend to disclose more to people whom we initially like, both in person and through social media (Rains, Brunner, & Oman, 2016; Sheldon, 2015).

Situational factors—The situations in which we encounter other people greatly affect how much we like them. It has been suggested, for example, that we like people when we experience rewards while in their presence (Huston, 2013). Furthermore, a shared humorous experience seems to be a powerful way of forging closeness with a stranger (Becker, 2019; Treger, Sprecher, & Erber, 2013). The famous playwright Oscar Wilde once said, "Laughter is not at all a bad beginning for a friendship."

Physical attractiveness—People of all ages, even babies, prefer to look at and be near attractive people. Not surprisingly, then, physical attractiveness may affect likeability (Mitsuhiro & Kitaoka, 2016; Zhao et al., 2015). (See photo.)

Loving

Whereas liking someone involves a sense of fondness, loving is associated with a more extreme affection. When we *love* someone, we experience a strong, passionate attachment to that person. Some see loving as simply an extreme form of liking—with degree of attraction being the key distinction—whereas others see loving as a qualitatively different phenomenon (Berscheid & Regan, 2016).

Sergio Dionisio/Getty Images

New approach, same criteria **Two people meet in a speed dating program at Bondi Beach in Australia. Speed dating is a relatively new form of social engagement in which large numbers of men and women are rotated to meet many potential partners over a series of short three- to eight-minute "dates." What kinds of partners do speed daters choose most often? Those who are attractive and hold attitudes similar to those of the selectors.**

Let's first consider the question of what functions love serves. Freud viewed love as *sublimated sexual energy*—that is, a transformation of sexual desire into a more socially acceptable form (Marcuse, 2015). Evolutionary theorists emphasize love's role in pair-bonding as a means for propagating the species. According to these theorists, strong passionate attachments have ensured that over time, parents would stay together and raise their children together (Fletcher et al., 2015).

Still other theorists argue that love's most important value is to help provide companionship, emotional support, and even protection throughout the lifespan (Bar-Tur, Ifrah, Moore, & Katzman, 2019; Seppala, Rossomando, & Doty, 2013). The positive relational value of pets provides some of these values as well (Hoffmann, Lagerkvist, Gustavsson, & Holst, 2019), particularly for some during COVID-19 lockdowns (Hoy-Gerlach, Rauktis & Newhill, 2020). Loving relationships have in fact been associated with improved health (Robles et al., 2014; Loving & Slatcher, 2013). Such relationships provide us with people to confide in—and not being able to confide our troubles to someone has been associated with a host of health problems (Cornwell & Laumann, 2013). This may be one reason why recently widowed individuals are more vulnerable to disease than individuals of a similar age who have not lost a spouse (Holm, Berland, & Severinsson, 2019; Sorrell, 2012).

What are the building blocks of love? Decades ago, social psychologist Zick Rubin (1970) emphasized three elements of love: attachment, caring, and intimacy. *Attachment* refers to the individual's need or desire for the physical presence and emotional support of the other person; *caring* is a feeling of concern and responsibility for the person; and *intimacy* involves the desire for close, confidential communication with the other individual (Fehr,

2019).

Using this definition of love, Rubin (1973) designed a self-report scale that he hoped would be able to measure love and distinguish it from liking. The scale included *love* items, such as "If I could never be with ____, I would feel miserable" and "I feel I can confide in ____ about virtually everything," along with *like* items, such as "I think that _____ is usually well-adjusted" and "_____ is the sort of person whom I myself would like to be." In one study, Rubin had dating couples fill out this scale, alone and confidentially, focusing on their date partner in their ratings. He found that friends and lovers both scored high on the like items, but friends did not score high on the love items.

In another study, Rubin had volunteer couples come to his laboratory and sit across from each other while awaiting the start of the experiment. His assistants secretly observed the couples from behind a one-way mirror to determine which ones gazed into each other's eyes, a sign of love according to conventional wisdom. As expected, the partners who had scored high on Rubin's love scale gazed lovingly at each other more than did partners who had scored low on the scale.

Another psychologist, Robert Sternberg, previously discussed in Chapter 10, has proposed the **triangular theory of love**, which holds that love is composed of *intimacy*, *passion*, and *commitment* (Sorokowski et al., 2020; Sternberg, 2013, 2004, 1986). Here, *intimacy* refers once again to feelings that promote closeness and connection, *passion* involves intense desires for union with the other person, and *commitment* refers to the decision to maintain the relationship across time. According to Sternberg, the extent and quality of each of these three components determines the nature of a particular loving relationship.

> **triangular theory of love** a theory proposed by Robert Sternberg that love is composed of three elements: intimacy, passion, and commitment.

In fact, Sternberg distinguishes between eight kinds of relationship, each reflecting a particular combination of the three components (**Figure 13.12**). For example, purely *romantic* love consists of much intimacy and passion with little commitment. In contrast, couples who experience *companionate* love are high on intimacy and commitment but low on passion. Couples who experience *consummate* love are high on all three components; and those with *empty* love are high on commitment only. Sternberg also believes these relationships change over time, peaking at different points.

What determines *how* we love? Many theorists suggest that the way we express and experience love is a direct outgrowth of our early experiences with caregivers (Neto, 2020; Hazan & Shaver, 2004, 1994a, 1994b, 1987). For example, as we observed in Chapter 4, young children seem to express one of several kinds of attachment in their relationships with their parents (Ainsworth, 1979). It appears that adults display similar types of attachment in their romantic relationships. Using the attachment model, researchers Cindy Hazan and Phillip Shaver (2004) have proposed three types of lovers.

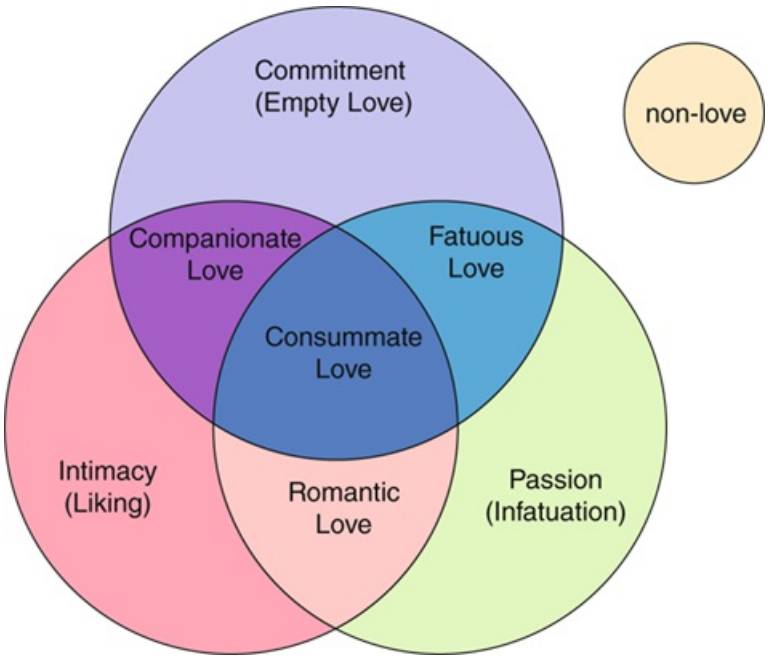

FIGURE 13.12 Sternberg's triangular theory of love **Sternberg's theory (1987) talks about the various possible combinations of intimacy, passion, and commitment and produces eight distinct types of relationship.**

Those with *secure* attachment styles find it relatively easy to become close to others and are comfortable depending on lovers and being depended on. They do not fear becoming too close or being abandoned.

Those with *avoidant* attachment styles are somewhat uncomfortable being close to others and have difficulty trusting others and depending on them. In fact, they become nervous when others want to become closer to them.

Those with *anxious-ambivalent* attachment styles worry that their lovers are less interested in closeness than they are. These insecure individuals are preoccupied with concerns that their partners do not really love them or will not stay with them. Sometimes their demands for security in relationships wind up pushing people away.

In their research, Hazan and Shaver found that approximately 53 percent of adults in romantic relationships display a secure attachment style, 26 percent an avoidant attachment style, and 20 percent an anxious-ambivalent attachment style.

Before You Go On

(Answers to Before You Go On may be found online in the Course Resources.)

What Do You Know?

13. What is groupthink and under what conditions is it most likely to occur?

14. How does altruistic helping behaviour differ from egoistic helping behaviour?

15. How does the presence of other people affect the likelihood that a bystander will

intervene on behalf of someone who needs help?

16. What are some of the biological underpinnings of aggressive behaviour?

17. What are the three components of Robert Sternberg's triangular theory of love and how do they interact in relationships?

What Do You Think? • Think about a relationship you have had with a friend—someone you really like. Analyze the development of that relationship with reference to some of the key factors discussed in this section.

Social Functioning

LEARNING OBJECTIVE 5

Describe the major findings of social neuroscience about regions of the brain particularly important to our social functioning.

Throughout this book, you have seen that with the help of brain-scanning procedures, researchers have tied many areas of psychological functioning, such as memory or emotions, to particular neural circuits—collections of neurons that communicate with each other. The study of social functioning is no different. Indeed, there has been so much work to uncover what happens in the brain when people are thinking and behaving socially that the field of study has been given a special title, *social neuroscience*, and the combination of brain regions that operate together when people function socially has also been given a special name in some circles, the "social brain."

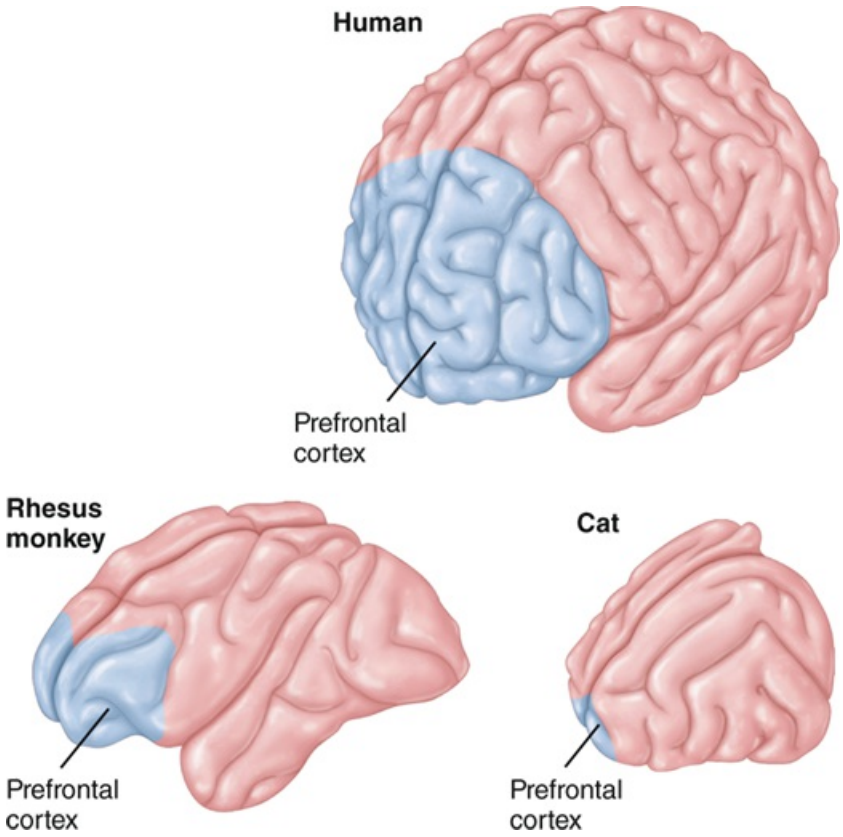

FIGURE 13.13 Across the species The prefrontal cortex of human beings is larger than that of other animals and is, at the same time, very active during social behaviour, suggesting that it plays an important role in human social functioning.

One of the early clues that helped researchers to identify regions of the brain that may be at work in social cognition and behaviour came from evolutionary psychology (De Jaegher, Di Paolo, & Adolphs, 2016; Stanley & Adolphs, 2013). Beginning with the observation that a unique and critically important area of human functioning is social cognition—particularly the ability to infer what is going on (intentions, feelings, and thoughts) inside the minds of other people—scientists decided to pay special attention to those regions that are newer and/or bigger in human brains than in the brains of other animals. Their suspicion was that these regions may be the ones that play key roles in social functioning.

Not surprisingly, several of the brain regions that, according to brain scans, are very active during social cognition and behaviour are indeed particularly large in the human brain. For example, the *prefrontal cortex*, the part of the frontal cortex that is closest to the front of the head, is much larger in humans than in other animals (see **Figure 13.13**). As we observed in Chapter 3, the entire frontal cortex is somewhat larger in the human brain than in the brains of less complex animals. But the prefrontal cortex is particularly larger (Delgado et al., 2016; Kanat, Heinrichs, & Domes, 2014).

Social cognitions and behaviours rely on many of the psychological functions that we have examined throughout this book. They require, for example, rapid identification of social stimuli and signals (for example, recognition of people), rapid retrieval of memories (to help us remember who is a friend and who is a foe), the ability to recognize the perspective

of others, anticipation of others' behaviours, experiences of emotion and empathy, and moral and other evaluations of situations (to help us decide, for example, whether prosocial behaviour is in order). Thus, some of the brain regions that are highly active during social functioning turn out to be ones related to language and thought, memory, and emotion (Fiske & Taylor, 2013). To date, social neuroscientists have identified the following brain regions as among the key players in social functioning:

Orbitofrontal cortex—a subregion of the prefrontal cortex, it is involved in social reasoning, reward evaluation, reading other people, and eliciting emotional states (Apps & Sallet, 2017).

Ventromedial prefrontal cortex—another subregion of the prefrontal cortex, it plays a key role in the processing of rewards and punishments, interpreting non-verbal social information (such as facial expressions), making social and moral assessments and decisions, and feeling empathy (Meyer, 2019; Roy, Shohamy, & Wager, 2012).

Insula—a region of the cortex that is located beneath the frontal cortex, it plays a key role in empathy and in reading others. The insula is activated when we observe others in physical or emotional pain and immediately feel that pain ourselves (Li et al., 2020; Harlé et al., 2012).

Amygdala—a brain region that is located in the temporal lobe, it is, as we have seen, actively involved in the control of emotions. In social functioning, it helps us to identify the emotional facial expressions of other people and to pay particular attention to stimuli that may be unpredictable, potentially rewarding, or potentially punishing (Yao, Xuan, Wu, & Sang, 2020; Becker et al., 2012).

We still have much to learn about how these and other regions operate together to help people function socially. Social neuroscientists are also still trying to identify the precise neural networks that enable us to so readily carry out the social cognitions and behaviours examined throughout this chapter.

Before You Go On

(Answers to Before You Go On may be found online in the Course Resources.)

What Do You Know?

18. What is social neuroscience and what is the "social brain"?

19. Which brain regions have been identified as particularly important to our social functioning?

What Do You Think? • If you were a neuroscientist looking for parts of the brain that are important to social functioning, how would you decide where to look first?

Summary

Social Cognition: Attitudes

LEARNING OBJECTIVE 1 Explain how attitudes form and change and what role they play in behaviour.

Attitudes are relatively stable and enduring evaluations of things and people. According to the ABC model, they have affective, behavioural, and cognitive components.

Parents play a major role in shaping children's attitudes. In older children, peers, teachers, and the media also exert an influence.

Leon Festinger proposed that people change their attitudes when they experience cognitive dissonance—a state of emotional discomfort that arises when a person holds two contradictory beliefs or holds a belief inconsistent with his behaviour.

The self-perception theory of attitude change minimizes the role of emotional discomfort and suggests that people simply infer what their attitudes are by observing their own behaviour.

The attitudes people express are not necessarily related to their behaviour. In part, this is because people sometimes misrepresent their attitudes. They may wish to express socially desirable attitudes, or they may not be aware of what their *implicit attitudes* really are.

Stereotypes and prejudice arise in part from the human tendency to identify with a group. Various explanations of prejudice come from evolutionary theories, realistic conflict theory, and social identity theory.

People use persuasion techniques to try to influence the attitudes of others. The central route to persuasion emphasizes the content of the message, while the peripheral route depends on more superficial appeals, such as the appearance of the spokesperson.

Social Cognition: Attributions

LEARNING OBJECTIVE 2 Discuss how people make attributions to explain their own behaviour and the behaviour of others.

Attributions, or causal explanations of behaviour, can be *dispositional* (internal) or *situational* (external).

People tend to attribute their own behaviour to situational factors and the behaviour of others to dispositional factors. The reliance on dispositional factors to explain others' behaviour is the *fundamental attribution error*.

According to the actor–observer effect, this discrepancy exists because people make situational attributions as actors and dispositional attributions as observers.

People sometimes attribute only their failures to situational factors and attribute their successes to dispositional factors, called the self-serving bias.

Social Forces

LEARNING OBJECTIVE 3 Describe the power of conformity and obedience in shaping people's behaviour.

Society establishes rules, or *norms*, about how people are supposed to act. *Social roles* are sets of norms ascribed to particular social positions. Norms and roles are critical to the smooth functioning of society, but also place limits on individuals.

Conformity is the tendency to yield to real or imagined group pressure. In a famous series of experiments, Solomon Asch found that 75 percent of research participants yielded to implicit group pressure to conform to an incorrect judgment.

Unlike conformity, obedience involves following direct orders, usually from an authority figure. Experiments by Stanley Milgram found that 65 percent of subjects continued to follow orders to administer what they believed to be dangerous electric shocks.

Social Relations

LEARNING OBJECTIVE 4 Review major concepts in the areas of group dynamics, helping behaviour, aggression, and interpersonal attraction.

The *social facilitation* effect occurs when the presence of others enhances a person's performance. Research shows that this effect holds for simple, well-learned tasks; but the presence of others can impair performance on more complicated tasks.

With social loafing, people in a group exert less effort on a task than they would if performing the task alone.

Group polarization is a phenomenon in which group discussion intensifies the already-held opinions of group members and produces a shift toward a more extreme position.

Groups with certain characteristics—a strong similarity among members, high group cohesiveness, high perceived threat, elevated stress, insulation from outside influence, and a directive leader—may become victims of groupthink, a faulty decision-making process in which group members strive for unanimity at the expense of realistically appraising alternative courses of action.

Helping behaviour is of two types: altruism, which is motivated by concern for others, and egoistic helping behaviour, which is motivated by a desire to reduce one's own distress or receive rewards.

People are more likely to engage in helping behaviour when alone than when in the presence of others. Theorists propose that the presence of others may create a diffusion of responsibility, in which no single individual feels personal responsibility for acting.

Aggression describes a broad range of behaviours intended to do harm to another. Aggression has some biological underpinnings. In addition, the frustration-aggression hypothesis proposes that aggression arises in response to frustration.

Factors that lead to liking another person include similarity, proximity, self-disclosure, situational, and physical attractiveness.

One description of love includes three elements: attachment, caring, and intimacy. Another, Sternberg's triangular theory of love, holds that love is composed of intimacy, passion, and commitment, which combine in varying degrees.

Similar to young children, adults display three types of attachment in love relationships: secure attachment, avoidant attachment, and anxious-ambivalent attachment.

Social Functioning

LEARNING OBJECTIVE 5 Describe the major findings of social neuroscience about regions of the brain particularly important to our social functioning.

Social neuroscience is the specialty of neuroscience that studies how the brain works during social functioning. Social functioning is so important and uniquely human that social neuroscientists have given the name "social brain" to the combination of brain areas that are particularly active in social functioning.

The orbitofrontal cortex, ventromedial prefrontal cortex, insula, and amygdala all have been identified as especially important in social functioning. Researchers continue to try to pinpoint neural connections related to social functioning.

Self-Study Questions

Multiple Choice

1. A woman who is participating in a march to draw attention to an issue that is important to her is demonstrating the _____ component of attitudes.

- **a.** affective
- **b.** behavioural
- **c.** cognitive
- **d.** perceptual

2. We are most likely to persuade someone to help us with a time-consuming, unappealing task if we

- **a.** ask the person to help with a smaller task first.
- **b.** begin with a weak argument, then follow up with a strong one.
- **c.** forewarn the person that a request is coming.
- **d.** make sure the person is in a bad mood.

3. The fundamental attribution error occurs when we overestimate _____ when thinking about the causes of other people's behaviour.

- **a.** dispositions
- **b.** extenuating circumstances
- **c.** situations
- **d.** temporary factors

4. A(n) _____ norm is one that is not taught directly, but that people tend to pick up on.

- **a.** descriptive
- **b.** explicit
- **c.** implicit
- **d.** injunctive

5. In Asch's original study of conformity, about what percentage of participants conformed

(gave a response that they knew was incorrect) at least once?

a. 1 percent

b. 37 percent

c. 66 percent

d. 75 percent

6. Group members who are each mowing the grass on their assigned section of a golf course are engaging in a(n) _____ task.

a. additive

b. conjunctive

c. disjunctive

d. divisible

7. The Kitty Genovese murder and subsequent research helped psychologists understand that when people fail to help others, it is usually because they

a. are apathetic and unconcerned with other people's well-being.

b. fail to see the benefits of helping others.

c. get caught up in a powerful social situation.

d. have valid reasons for failing to help.

8. According to Sternberg, a high degree of intimacy, passion, and commitment is characteristic of _____ love.

a. consummate

b. fatuous

c. infatuated

d. romantic

9. The part of the brain that is most directly related to our experience of both empathy and the ability to read others is the

a. amygdala.

b. hypothalamus.

c. insula.

d. orbitofrontal cortex.

10. An Olympic coach is training an athlete and wants to see the athlete's time improve. You tell the coach that according to the _____ effect, he would be better off to get actual people to run against the athlete in training.

a. groupthink

b. social facilitation

c. group polarization

d. social loafing

Fill-in-the-Blank

1. Festinger's research showed that behaviour leads to attitude change only when there is no other good reason, or _____, for the behaviour.

2. Attitudes are more likely to predict behaviour when the attitudes are high in strength and/or _____.

3. If a teacher assumes that a student is always late for class because the student is lazy and unorganized, the teacher is making a(n) _____ attribution for the student's behaviour.

4. In a study of cultural influences on attributions, it was found that the characteristic of _____ led Chinese participants to focus on situational causes of behaviour more than American participants did.

5. Groups with fewer than _____ members do not typically show a conformity effect.

6. Milgram told his research subjects that they were participating in a study of the effects of _____ on learning.

7. Zajonc proposed that the presence of others increases our physiological _____, which then improves or impairs task performance depending on the task and the person.

8. When others are present, we may feel that we do not bear the burden of responsibility to act. This phenomenon is known as diffusion of _____.

9. Neuroscientists have found that the _____ cortex is important to social functioning and is larger in humans than in other species.

10. Those with _____ attachment styles find it relatively easy to become close to others and are comfortable depending on lovers and being depended on.

CHAPTER 14
Stress, Coping, and Health

andresrimaging/iStockphoto.com

CHAPTER OUTLINE

What Is Stress?

LEARNING OBJECTIVE 1 Define stress, describe the ways in which people experience stress and the kinds of situations that typically cause stress.

Responding to Stress

LEARNING OBJECTIVE 2 Describe the physiological, emotional, and cognitive responses to stress, and explain how individual responses to stress differ.

Coping with Stress

LEARNING OBJECTIVE 3 Discuss and evaluate several ways in which people cope with stress.

Stress and Health

LEARNING OBJECTIVE 4 Explain how stress can cause physical illness, and discuss situations in which stress may be beneficial.

Posttraumatic Stress Disorder

LEARNING OBJECTIVE 5 Describe the symptoms and causes of posttraumatic stress disorder, and discuss some risk factors for developing it.

"What am I doing?" thought Ashley as she sat at her desk, unable to concentrate. "My English paper is due on Wednesday, but I'm just staring at a blank computer screen. I know I need to get started, but I can't concentrate on this paper." All sorts of thoughts are flying through Ashley's head—each one makes her chest tighten and makes her want to curl up into a ball with her eyes shut.

She has to leave for her job in less than an hour. She desperately needs the bus to be on time. Chris, her boss, has told her that if she is late again, he'll "have to find someone more reliable." And then there is the email she just got from her parents asking—once again—about her grades. She is the first child in her family to go to university, and her parents have been driving her crazy. She's glad that they are so excited, but don't they realize that asking for weekly updates only puts more pressure on her?

In fact, things aren't going so well in some of her classes. She's good at chemistry, but she finds English, especially writing, very difficult. "Just work harder," her parents tell her, as if she wasn't trying as hard as she could. Her public speaking class is a disaster: she actually had to leave in the middle of her last speech, fighting back tears.

The more trouble she has, the more she feels like just going out with her friends at night. In fact, she's gone out every night this week, always telling herself, "I'll get started on my paper tomorrow." Even though she knows she can't put her paper off any longer, she has agreed to see a movie tonight after work with some people from school.

Then there is the recent breakup with her boyfriend, Jason. She feels bad about the way their relationship ended. One night when she was late for work and in a panic, he called her and teasingly refused to let her off the phone. After a few minutes, she called him a jerk and hung up on him. It wasn't the first time she had lashed out at him, and even though she tried to apologize the next day, he said he didn't want to deal with her moods anymore.

"All right, let's try to get it together," she tells herself. "Come up with a game plan." She decides to jog to the restaurant, avoiding bus delays and getting some exercise to boot. Moreover, in the few minutes she has before she must leave for work, she forces herself to start typing. Before too long, she has two paragraphs on the screen. "Not bad," she thinks, "at least it's a start." She is finally thinking and acting constructively.

You don't need a textbook to tell you that Ashley is experiencing stress. After all, you may have been, or are, in a similar place—too much to do, too little time, too many expectations, too little certainty about what to do next. Ashley is obviously feeling stress because she has lots of work to do and is running out of time. But she also has feelings of stress connected to something otherwise pleasant—the opportunity to socialize with friends. Things as common as writing an English paper, as pleasant as the prospect of an evening out, or as awful as a life-threatening medical condition can prompt feelings of stress.

Stress affects us both physically and psychologically (see photo). Recall how you felt the last time you were stuck in a traffic jam on your way to someplace important. Chances are you had physical and psychological reactions—you may have been frustrated and angry, your stomach may have been tied up in knots, and you may even have pounded on the steering wheel or yelled. Chronic stress from our modern world can even damage our health.

The effects of stress on psychological and physical health have made it a subject of major research. Some researchers are trying to clarify what makes situations stressful. Others are studying how stress affects the body. Still others are trying to figure out what responses help people to cope effectively with stress and lessen its toll. This chapter examines what researchers have learned about the sources and effects of stress. It also looks at ways to deal with stress, noting that certain kinds of behaviour—such as Ashley's jog to work or her

decision to simply start writing her paper—can help people reduce stress or cope with it positively.

What Is Stress?

LEARNING OBJECTIVE 1

Define stress, describe the ways in which people experience stress and the kinds of situations that typically cause stress.

You probably use the word *stress* all the time. We talk about being stressed, feeling stress, or about stressful events and situations, but have you thought about what it actually means? The term has been defined in various ways, so we will begin our examination of stress with a definition. We will then discuss the ways in which people experience stress and the kinds of situations that cause stress.

Stress and Stressors

Stress is a state brought on by any situation that threatens or appears to threaten a person's sense of well-being, thus challenging the person's ability to cope. A situation or circumstance that triggers the stress response is called a **stressor**. Stressors can be *acute* or *chronic*. An **acute stressor** is short term and has a definite endpoint—for example, a near miss in heavy traffic. A **chronic stressor** is long term and often lacks a definite endpoint—for example, dealing with a high-pressure job (see photo) or being unemployed over time.

stress state brought on by any situation that threatens or appears to threaten a person's sense of well-being, thus challenging the individual's ability to cope.

stressor a situation or circumstance that triggers the stress response.

acute stressor a stressful situation or circumstance that happens in the short term and has a definite endpoint.

chronic stressor a stressful situation or circumstance that is more long term and often lacks a definite endpoint.

Brendan McDermid/Reuters - Images

Anxious moments A trader on the floor of the stock exchange watches the numbers on the board anxiously, waiting desperately for a favourable moment to make his move.

Obviously, our definition of stress is rather broad—literally anything can cause stress. The breadth of the definition takes into account the wide range of situations that people experience as stressful, from daily pressures at work and school to more catastrophic events, such as health crises, natural disasters, and terrorist attacks. At the same time, the definition calls attention to the emotional experience of stress and how individualized stress is.

A number of psychological factors help to determine the degree to which something will cause us to experience stress. In fact, stress is actually derived more from how we *appraise* the situation than from the situation itself (Folkman, 2013a, 2013b; Lazarus & Folkman, 1984). That is, our appraisal of our ability (or inability) to cope with a situation is an important factor in how much stress we experience. For example, two people attending a party of mostly strangers may approach the party with differing levels of stress. One person may view the situation as exciting, enjoying the idea of meeting a lot of new people. Another person might instead view the same situation as highly stressful, feeling very threatened by the idea of meeting a large number of new people. In each instance, each

person appraises the situation based on their perceived ability to cope. It is therefore our *perception* of threat that triggers the emotional state we connect to stress. If we do not perceive a situation as threatening, we will not feel particularly stressed. We will soon look at more psychological factors in stress, but before that, let's examine the different ways that people experience stress.

Ways of Experiencing Stress

By definition, people who experience stress feel threatened and challenged. But these threats and challenges come in different forms. Certainly, soldiers in combat, students whose grades are falling, and children whose parents are unhappy with them face different kinds of stress. Individuals who experience stress often have one of four kinds of experiences that lead to feeling stressed. These are: *frustration*, *pressure*, *conflict*, and *danger*. These kinds of stress are not mutually exclusive even though we consider them separately here. As you read through the next few sections, think about how these various aspects of the stress experience might go together.

Feeling Frustrated

You finally find a parking spot, and someone pulls into it just ahead of you. You try to register for a course, and it is full. You work hard, but you get a C on the test. Whenever we find ourselves thwarted in the pursuit of a goal, we experience **frustration**. Life is full of frustration; it is one of our most familiar kinds of stress. Frustration can be caused by acute stressors, such as those in the situations just described, and by chronic stressors. Persons who have chronic illnesses or disabilities, for example, are likely to feel frustrated that they cannot do more. All of these experiences are bound up with the notion of trying to achieve something and having a barrier to our progress (Beehr, 2014). Barriers to progress generate stress.

frustration an emotion people experience when thwarted in pursuit of a goal.

Feeling Pressured

We all encounter a certain amount of **pressure**—the expectation that we should act in a certain way. The pride felt by Ashley's parents over their daughter's admission to university is a source of pressure, and her boss's expectation that she should arrive at work on time is another.

pressure an expectation or demand that someone act in a certain way.

Pressure often comes from within. Some individuals have such high expectations of themselves that they are constantly under self-imposed stress. Think of the sources of pressure in your own life. What standards do you set for yourself academically and socially? Are you driven to achieve in athletics, music, or *Call of Duty*? How much pressure do you experience as a result of such expectations? For some, stress that comes from within is often more difficult to cope with than stress imposed by others. It may not be easy to meet the deadline for turning in a term paper, but at least when you do so, the pressure will

be off. By contrast, if you set yourself a rigid standard of perfection, you may never find release from this internal pressure.

QMI Agency

A costly error **A dejected Steve Smith immediately after scoring on his own goal, an error that led to the Edmonton Oilers losing the Stanley Cup Western Conference semi-final game back in 1986.**

Pressure also varies along with the task and situation. One set of studies, for example, demonstrated that participants experienced greater stress when performing complex tasks in front of an audience, but that they performed significantly better without the pressure of an audience (Oudejans et al., 2017). Focusing on the specific task they are performing can also reduce perceptions of stress (Buma, Bakker, & Oudejans, 2014). Still other research has found a strong correlation between feelings of pressure and symptoms of distress, indicating that perceived discrimination is associated with increased levels of depression and an increased number of medical diagnoses (Todorova et al., 2010).

Sports and Pressure

In the 1986 Western conference semi-finals between the Edmonton Oilers and the Calgary Flames, Oiler Steve Smith made a heartbreaking mistake. The game was tied 2–2 in the third period of the seventh and deciding game, and Smith was carrying the puck out from behind his own net with no one checking him. He attempted a cross-ice clearing pass that somehow bounced off the back of his own goaltender (Grant Fuhr) and ended up in his own team's net. Calgary knocked the two-time Stanley Cup-winning Oilers out of the playoffs. Smith was devastated. It also happened to be his birthday, and he has since said that now he thinks of the goal every time he blows out his birthday candles (see photo).

What happened to Smith and to other athletes who have made mental errors in other high-pressure situations? When does pressure help athletic performance and when does it impair it? These questions have been the subject of much study. A number of explanations

have been offered, but a clear understanding of the effects of pressure on athletes remains elusive (Weinberg & Gould, 2015).

We do know that performance pressure results when athletes feel strongly about the outcome of an event and believe that their own performance will have an impact on that outcome (Bali, 2015). We also know that this pressure can result in increased physiological and psychological arousal. But researchers cannot predict the precise relationship between such arousal and performance.

For years, psychologists believed that the relationship probably follows the principle of the *Yerkes-Dodson law*. As we discussed in Chapter 11, this psychological "law," developed in 1908 by psychologists Robert Yerkes and John Dodson, holds that performances on tasks of any kind increase along with physical or mental arousal—up to a point—but once an optimal, moderate level of arousal is passed, performances begin to decrease. Applying this law to athletic performances, it is generally believed that if an athlete is not aroused, his or her performance will suffer, and that if he or she is too aroused, performance will also suffer. Optimal performance is thought to occur only in the presence of a moderate level of arousal (Yerkes & Dodson, 1908).

Over the years, research has better supported an alternative version of the Yerkes-Dodson law, particularly in the realm of athletic performance. Recall from Chapter 11 that this alternative model holds that the level of arousal at which optimal performance occurs is a *zone* (not a single point) and varies from athlete to athlete. Some cross-country runners, for example, will perform best if they take naps right before a race, while their teammates will do best if they listen to inspiring music, visualize their opponents, and engage in intense stretching exercises before the race (Bali, 2015; Rathschlag & Memmert, 2015).

A different line of research suggests that coaches can play a large role in helping athletes cope with performance pressure. Since anxiety tends to be lowest in athletes who believe in their performance abilities and are self-assured, research suggests that coaches can help by facilitating feelings of confidence—for example, by providing frequent, genuine encouragement and by fostering a positive environment, regardless of whether things have gone well or mistakes have occurred (Beaumont, Maynard, & Butt, 2015; Pineschi & Di Pietro, 2013). Here again, however, effective methods vary from athlete to athlete.

Feeling Conflicted

The stress Ashley feels is not simply the result of pressure from her parents. It also results in part from her desire to do two things at the same time: (1) study to earn good grades, and (2) have time to go out with her friends. In situations such as this, we experience **conflict**—discomfort brought about by two or more goals or impulses that we perceive to be incompatible. There are three basic types of conflict: *approach–approach*, *avoidance–avoidance*, and *approach–avoidance* (see **Figure 14.1**) (Miller, 1959; Lewin, 1935).

conflict discomfort brought about by two or more goals or impulses perceived to be incompatible.

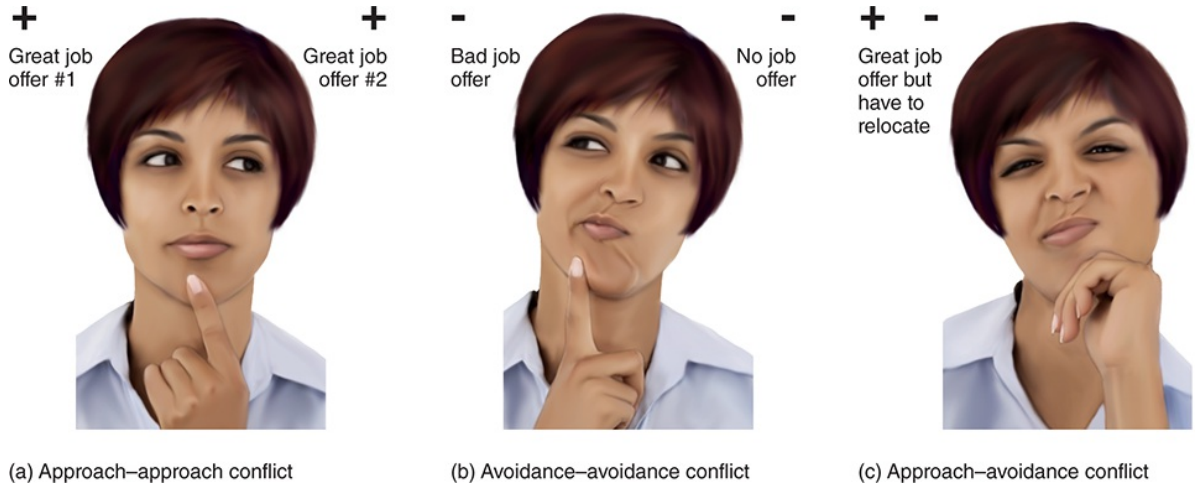

FIGURE 14.1 Three basic types of conflict that can lead to stress

As its name implies, **approach–approach conflict** occurs when we must choose between two equally desirable options. Should we have the chocolate cake or the blueberry pie? Should we buy the red backpack or the black one? In many cases, approach–approach conflicts are easy to resolve (you can't really lose with either choice), and so they are not especially stressful.

Avoidance–avoidance conflicts are somewhat more stressful because here the choice is between two equally undesirable outcomes. Should you clean the garage or do the laundry? You may be tempted to do neither. If you deal with this kind of conflict by deciding to procrastinate, postpone, or avoid the choice, however, you are particularly likely to experience stress (Sirois & Kitner, 2015).

In an **approach–avoidance conflict**, any available choice has both desirable and undesirable qualities, rendering us ambivalent and indecisive. In some situations, this sort of conflict may involve only one choice with both positive and negative features. For example, if Ashley were to go out with her friends, she would enjoy herself, but she wouldn't be able to work on her paper. In other situations, more than one option may be involved. Should you buy a car that is expensive but fuel-efficient, for example, or a less expensive gas guzzler? Approach–avoidance conflicts are on display in many of our most agonizing decisions. Often people worry for some time about how to resolve them, and experience considerable stress along the way.

approach–approach conflict conflict that occurs when a person must choose between two equally desirable options.

avoidance–avoidance conflict conflict that occurs when a person must choose between two equally undesirable options.

approach–avoidance conflict conflict that occurs when any available choice has both desirable and undesirable qualities.

Feeling Endangered

Life-threatening situations understandably produce stress, making us feel endangered. The

adrenaline rush we experience when a car in front of us suddenly stops, forcing us to swerve and slam on the brakes, is characteristic of this kind of stress. Similarly, such stress is experienced by people who face combat or are trapped in a fire. Natural disasters and pandemics, such as the outbreak of COVID-19 in 2020, may also be life threatening and, in turn, stressful (see Psychology Around Us 14.1). Life-threatening situations created by people may also produce stress. Terrorism leaves individuals with feelings of uncertainty, sadness, and fear, making them vulnerable to the onset of stress disorders (Tracy et al., 2014; Zemishlany, 2017). Indeed, terrorism may have long-term psychological effects (see photo).

Carmen Taylor/AP Images

Stress and terror **The aftermath of life-threatening events, like the terrorist attacks of 9/11, might lead some New Yorkers to experience a sense of intense fear at the sight of a plane in the sky, or to cringe at the sound of a bus backfiring.**

Kinds of Stressors

Just as there are different ways of experiencing stress, there are different types of stressors. Indeed, stressors vary widely—from discrete life events to chronic stressors. Moreover, they can be mild, extreme, or anywhere in between. As you will see later in this chapter, what is stressful for one person may not be stressful for another. Still, there are several kinds of events that are likely to produce feelings of stress whenever they are experienced: daily hassles, such as traffic jams; life changes, such as the loss of a job; traumatic events, such as natural disasters; chronic negative situations, such as an enduring illness; and special socio-cultural conditions, such as racism. We will discuss each of these categories in turn, but as you know all too well, they may overlap or intersect.

14.1 Psychology Around Us

The COVID-19 Pandemic and Stress

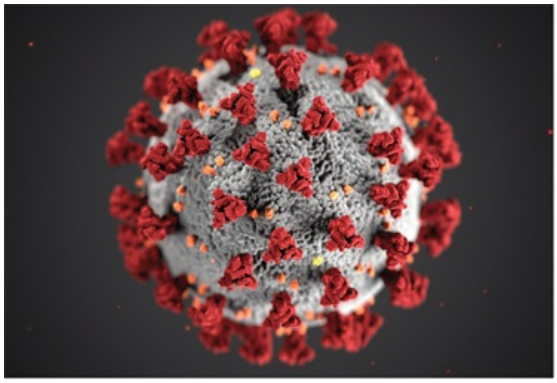
The global COVID-19 pandemic that began in 2020 introduced stressors into our society that hadn't been seen since the 1918 Spanish Flu pandemic more than 100 years ago. There was worry about the risk of catching COVID-19 and falling ill but that was just part of its stressful effects. The risk of unknowingly passing on the disease to a

vulnerable family member was also a significant stressor. Beyond those obvious stressors, families had to isolate, stay inside, and work from home. This put stress on close family relationships as many people were required to be in close proximity to each other for weeks or months on end. For health care workers on the front lines of the pandemic, their stresses were magnified as they worked in higher risk situations and then had to return home to their families after their shift (Carroll et al., 2020; Horesh & Brown, 2020; Pakpour, Griffiths, & Lin, 2020; Wu, Styra, & Gold, 2020).

Fortunately, the stressors of the isolation induced by the COVID-19 pandemic were offset somewhat by the Internet. While not the same as face-to-face contact, people were at least able to communicate with friends and loved ones on a regular basis via texting, video calls, and various meeting room software. For the elderly population, access to the Internet reduced stress (Nimrod, 2020), which was a small silver lining in an otherwise stressful crisis situation.

Seeking the support of others, whether in the form of professional assistance or just a sympathetic ear, was another way to ease the effects of stress of the pandemic. The knowledge that family and friends were available for social support eased the effects of stress in a couple of ways: by reducing the actual number and impact of stress-inducing situations, and by providing practical, problem-focused assistance when stressors arose.

In times of stress, self-disclosure, which is the sharing of emotions and experiences with others, can also help people deal with stress. “Getting something off your chest” with a friend is more than the simple venting of emotional baggage—it actually helps people to channel emotions into a cohesive narrative, thereby making stressors easier to deal with. The key to self-disclosure is ensuring that you have an attentive listener who is willing to help you when you need to unload your feelings around a stressor. While finding a listener in person during a pandemic may be challenging, social media can be a virtual space where self-disclosure about the stress of things such as COVID-19 can be mitigated (Zhang, 2017).



CDC/Unsplash.com

Bloomberg/Getty Images

Fox7

The COVID-19 pandemic created stress for many people worldwide Reaching out to friends and family, either in person or via online communication, are two strategies that can be used to mitigate the stress that is associated with the COVID-19 pandemic. Here we see people taking advantage of the stress relief that nature can bring by spending time outdoors either exercising or sitting within social distancing circles in a park.

Daily Hassles

Probably the most familiar sources of stress are **daily hassles** (also called micro-stressors)—the everyday annoyances that leave us feeling upset and at the end of our rope. These stressors can range from minor irritations, such as lost keys or an overly talkative co-worker, to major problems, such as intense work pressure or conflict with a romantic partner. Some daily hassles seem to be universally upsetting, including time pressures, cash-flow problems, feelings of being cheated after making a purchase, conflicts with romantic partners, mistreatment by friends, and poor evaluations at work.

> **daily hassles** everyday annoyances that contribute to higher stress levels; also known as *micro-stressors*.

Over time, daily hassles can add up. They may become particularly stressful when they occur in combination with other stressors, leaving individuals overwhelmed (Falconier et al., 2014; Schönfeld et al., 2016). A hot day may not be particularly stressful by itself, but combine it with waiting in a long line to renew a driver's licence, holding a crying child, and

having a blister on your heel, and you may wind up feeling exasperated and depleted. In fact, data suggest that the accumulation of daily stressors often leads to increased health risks (Piazza et al., 2013; Wirtz & von Känel, 2017). Meanwhile, research has found that engaging in healthy living habits decreases the impact of university or college stress among students (Fogel & Pettijohn, 2013).

It turns out that the impact of daily hassles on health is often greater than that of a major life event. This is because ongoing stress may impair our immune system responses, as we shall see later. Indeed, one study found that people who face daily commutes in heavy traffic are particularly likely to miss work because of colds and flu (Koslowsky, Kluger, & Reich, 2013)—illnesses that can result from stress-induced changes in the immune system.

Researchers have developed several measures of daily hassles. Psychologist Richard Lazarus and his colleagues developed one of the first, the *Daily Hassles Scale*, in which subjects are asked to consider a list of hassles, indicate which ones they had experienced over the past month, and report how stressful each event felt (Kanner et al., 1981). Measuring the impact of daily hassles is difficult, because people vary widely in how they experience and weigh such stressors (Kohn, 1996 ; Graf, Ramsey, Patrick, & Gentzler, 2016).

Some scales have targeted the experiences of college and university students and asked about both daily hassles and major stressful events (D'Angelo & Wierzbicki, 2003; Kohn, Lafreniere, & Gurevitch, 1990; Vogel & Schwabe, 2016). Feelings of stress tend to be strongest just before an exam and continue (though to a lesser extent) as students wait to receive their grades and as they later try to cope with the results (Strack & Esteves, 2015; Sweeny & Howell, 2017; Zwettler et al., 2018). (See photo.) See **Table 14.1** to review items on the Undergraduate Stress Questionnaire (Crandall, Preisler, & Aussprung, 1992).

TABLE 14.1

Undergraduate Stress Questionnaire

Source: Undergraduate Stress Questionnaire. Crandall, C. S., Preisler, J. J., & Aussprung, J. (1992). Measuring Life Event Stress in the Lives of College Students: The Undergraduate Stress Questionnaire (USQ). *Journal of Behavioral Medicine, 15*(6), 627–662.

Has this stressful event happened to you at any time during the last 2 weeks? If it has, please check the space next to it. If it has not, please leave the space blank.	
Lack of money	No sex for a while
Someone broke a promise	Someone cut ahead of you in line
Death (family member or friend)	Broke up with boyfriend/girlfriend
Dealt with incompetence at the registrar's office	Tried to decide on major
Couldn't concentrate	Felt isolated
Had a lot of tests	Had roommate conflicts
Thought about unfinished work	Chequebook didn't balance
Someone did a "pet peeve" of yours	Visit from a relative and entertained them

It was finals week	Someone you expected to call did not
Had an interview	Holiday
Had projects, research papers due	Sat through a boring class
Did badly on a test	Favourite sporting team lost
Couldn't finish everything you need to do	Thought about the future
Heard bad news	

These are a few of the items from this measure. If you would like to see and/or complete the whole measure, you can download it here: https://utulsa.edu/wp-content/uploads/2014/12/Undergraduate-Stress-Questionnaire.pdf (via Undergraduate Stress Questionnaire Link).

If you are concerned about how many stressful life events you have checked, you can contact your college or university counselling or wellness centre or check out some stress management resources on Health Canada's website: www.canada.ca/en/public-health/services/chronic-diseases/mental-illness/deal-most-effectively-stress.html

14.1 Indigenous Experiences

Life Changes

Robert Tomah was 9 years old in June 1966 when his father died. By early September, he was taken to the Lejac Residential School in the Fraser Lake area of British Columbia. Before entering the school, Robert spoke only Sikanni, lived a nomadic lifestyle with his immediate and extended family, and had never lived outside of the bush, trapping and travelling the waterways in riverboats. He and his brother were sent by plane to the school, away from their mother and most of their relatives. He said that "right away everything looked different to us." He had never seen a car or a street. He said that on the surface, the new life was glamorous but that even as a child he knew that "something hideous [was] hidden under all that glamour." He was initially trusting of everyone. He loved and trusted his parents and assumed that all adults were like them. He was quickly disabused of this assumption. Within hours of his arrival at the school he was cuffed, slapped, and struck for not understanding what was being said to him in English, which he did not speak or understand. Robert and his brother were told by cousins at the school that they had to stop speaking the Sikanni language because the priests and nuns felt that their language was "satanic." Robert and his brother had their heads shaved and their "bush clothes" taken away. They went to bed hungry every night. Eventually Robert was sexually abused by one of the nuns at the school. He recollects, "something happened to me. My trust was gone." He was frustrated and scared. "There was a lot of anxiety." He learned to lie and to blame others. "I began to deny myself… That first year was really hard because I couldn't communicate, and I couldn't understand." (Legacy of Hope Foundation, 2020)

Handout/Reuters

Hair as a source of power and strength **Children were considered "dirty savages" by many of those working in the residential schools. As a consequence, most children were given a haircut immediately upon arrival. Their hair, which, for many, carried important spiritual significance, was thrown into the garbage, and was kept short for the duration of their stay.**

Critical Thinking Questions

Life changes are a common source of stress. What life changes did Robert Tomah experience within a year that would have made him especially susceptible to stress?

What physiological responses to stress do you feel Robert would have likely suffered in that first year at the residential school?

Given the relationship between stress and illness, what would you predict might be some of the outcomes Robert experienced as an adult? Check to see whether you were correct at https://legacyofhope.ca/en/wherearethechildren/stories/tomah/.

Change

Another common source of stress is change. Those early weeks in a new school, for example, are usually quite stressful, even if they are also exciting. In the first weeks of college or university, students need to figure out what classes to take, where classrooms are located, what is expected of them, and where to buy books (as well as how to pay for them). At the same time, they are meeting many new people. Trying to find our way in new relationships can be even more complicated and challenging than finding our way to class (Gale & Parker, 2014).

damircudic/iStockphoto.com

Feeling stressed **The first set of midterm exams for first-year post-secondary students are often quite stressful.**

Life changes—shifts in life circumstances that require adjustment of some kind—were among the first sources of stress ever studied. In 1967, investigators Thomas Holmes and Richard Rahe set out to develop a way to systematically measure how much stress people experience. They compiled a list of 43 events that were likely to change a person's life and therefore cause stress. These events ranged from the death of a spouse, to minor violations of the law, to taking a vacation (note the similarity of these items to those on the Undergraduate Stress Scale, which was adapted from the Holmes Rahe scale). Based on ratings by participants, the researchers assigned a point value to each event, ranging from 1 to 100 points, or *life-change units (LCUs)*. The point value for each event corresponded to the amount of upset and adjustment the event typically produced. The death of a spouse received a score of 100 LCUs on the scale, for example, whereas a change in responsibilities at work was 29 LCUs, and taking a vacation came in at 13 LCUs.

life changes shifts in life circumstances that require adjustment of some kind.

With this 43-item list, called the *Social Readjustment Rating Scale (SRRS)*, Holmes and Rahe set about conducting studies on the impact of stress on people's lives. First they had individuals complete the scale to determine how much stress they were under. Participants were asked to check off all those events that had occurred in their lives over a certain time period, usually the past year. Then they added up the total number of life-change units, with the sum indicating the amount of stress the person had been under. A total score of 150 LCUs or less indicated relatively little stress; 150 to 199 indicated mild stress; 200 to 299 suggested moderate stress; and over 300 LCUs pointed to major life stress. Holmes and Rahe claim that those individuals who score over 300 are more likely to experience physical illness than those who score below 150 points. The life events from the SRRS and their ratings are listed in **Table 14.2**. Notice that a life-changing event need not be an undesirable one. A number of the events on the SRRS are positive, and some can be either

positive or negative. A change in living conditions, for example, may reflect a move upward or downward in life.

TABLE 14.2

The Social Readjustment Rating Scale

Source: Reprinted from Holmes & Rahe (1967). The Social Readjustment Rating Scale. *Journal of Psychosomatic Research*, Vol. III, 213–218. With permission from Elsevier.

To score your susceptibility to stress on this scale, add up the life change units for the events you experienced in the last year. Scores of 150 or less indicate little stress; 150–199 mild stress; 200–299 moderate stress; and over 300 major life stress.

Life Events	Life Change Units	Life Events	Life Change Units
Death of spouse	100	Son or daughter leaving home	29
Divorce	73	Trouble with in-laws	29
Marital separation	65	Outstanding personal achievement	28
Jail term	63	Spouse begins or stops work	26
Death of a close family member	63	Begin or end school	26
Personal injury or illness	53	Change in living conditions	25
Marriage	50	Revision of personal habits	24
Fired at work	47	Trouble with boss	23
Marital reconciliation	45	Change in work hours or condition	20
Retirement	45	Change in residence	20
Change in health of family member	44	Change in schools	20
Pregnancy	40	Change in recreation	19
Sex difficulties	39	Change in church activities	19
Gain of a new family member	39	Change in social activities	18
Business readjustment	39	Mortgage or loan for lesser purchase (car, major appliance)	17
Change in financial state	38	Change in sleeping habits	16
Death of a close friend	37	Change in number of family get-togethers	15
Change to different line of work	36	Change in eating habits	15
Change in number of	35	Vacation	13

arguments with spouse			
Mortgage or loan for major purchase	31	Christmas	12
Foreclosure on mortgage or loan	30	Minor violations of the law	11
Change in responsibilities at work	29		

Think back to our chapter opener, where we learned that Ashley recently broke up with her boyfriend, an event that would receive a score of 65 LCUs on Holmes and Rahe's scale. In addition, she has been experiencing troubles with her boss (23 LCUs), school pressures (39 LCUs), and new social activities (18 LCUs). Since she is a relatively new student, we can assume that she changed schools (20 LCUs) and residences (19 LCUs) fairly recently. Add in her outstanding personal achievement of being the first in her family to go to university (28 LCUs), and her LCU score totals 212—a moderate level of stress over a short period of time.

We pointed out that the Social Readjustment Rating Scale includes positive as well as negative life events (see photo). Nevertheless, the scale has been criticized for looking at many more negative events than positive ones and for not including events that do not occur, like not getting a job or promotion you applied for, and for potential differences in the perception of these stressors across cultures (McLean & Link, 1994; Noone, 2017). It is also missing levels of daily background stress that may influence how we respond to the stressors in this scale, thus, the scale may not give a complete picture of the effects of life change on stress levels (Terrill, Gjerde, & Garofalo, 2013).

As mentioned in the last paragraph, another shortcoming of the SRRS is that it does not apply equally to all populations. In developing the scale, Holmes and Rahe sampled mostly Caucasian Americans. Fewer than 5 percent of their participants were African Americans, and none were Native Americans. Subsequent research has shown this bias to be particularly problematic because Caucasian Americans and African Americans often rank life events differently. For example, although both groups rank the death of a spouse as the most stressful life event, African Americans rank personal injury or illness and major changes in work responsibilities or living conditions much higher than do Caucasian Americans (Jackson, 2013; Komaroff, Masuda, & Holmes, 1989, 1986). Similarly, certain types of events, such as the death of a family member, loss of a job, credit problems, and change in residence, are generally more stressful for women than for men (Miller & Rahe, 1997). Alexandra Robinson (2013) at the University of Calgary showed that women from Canadian ethnic minorities experience more psychosocial stress during pregnancy than do non-minority group members.

Digital Vision/Getty Images

Even positive changes can be stressful **Even though they are happy events, marriages produce a high degree of stress according to research using the Social Readjustment Rating Scale.**

As described by Lawrence Kirmayer of McGill University, over the past decades Canada's Indigenous population has experienced a broad and unique array of additional stressors. These include residential schools and the "60s scoop," in which a great many Indigenous children were removed from their communities and placed in non-indigenous foster homes away from family and Indigenous culture and community (see Indigenous Experiences 14.1). This has led to a broad range of additional stresses and challenges that are all parts of their social adjustment stress profiles. As a result, the Indigenous population experiences increased interpersonal problems such as substance abuse, depression, and suicide, as well as increased social problems including high rates of sexual abuse, family violence, and incarceration (Chachamovich et al., 2013; Fraser et al., 2015; Kirmayer, Simpson, & Cargo, 2003).

Life Change and Illness

Holmes and Rahe found that the LCU scores of sick people during the year before they became ill were considerably higher than those of healthy people (Holmes & Rahe, 1989, 1967). In fact, as stated above, if a person's life changes totalled more than 300 LCUs over the course of a year, that person was likely to develop a serious health problem.

The SRRS has been revised by researchers over the years (Hobson & Delunas, 2001; Hobson et al., 1998; Miller & Rahe, 1997). Using various scales, studies have tied a variety of life stressors to a wide range of physical problems, from upper respiratory infection to cancer (Baum, Trevino, & Dougall, 2011; Rook, August, & Sorkin, 2011; Renzaho et al., 2013; Calvo & Morrison, 2016). Generally, the greater the amount of life stress, the higher the likelihood of medical illness. Some researchers have even found a relationship between stress and death. Widows and widowers, for example, have an elevated risk of death during their period of bereavement (King et al., 2017).

Jim Young/Reuters - Images

Early separation **This soldier consoles his young daughter prior to his departure for Afghanistan. Research suggests that family military separations of this kind often take an enormous emotional toll on the children who are left behind.**

Lifespan Development and Stress

Although feelings of stress may be similar for both young and old people, the life changes that evoke these feelings apparently differ widely from age group to age group. As you have just seen, the most powerful stressors (in decreasing order) on the SRRS, a largely adult scale, are death of a spouse, divorce, marital separation, jail term, death of a close family member, and personal injury or illness. But how does stress affect younger age groups?

Researchers have developed special scales to measure life events and stress among traditional college and university students (Crandall et al., 1992; Renner & Mackin, 2002; Slavich & Toussaint, 2013). They have found that the most stressful life event for this population is the death of a family member or friend, much like the top life stressor for adults. Beyond this event, however, the leading life stressors for college and university students are ones that are tied to post-secondary life. They are (again in decreasing order) having to take multiple tests, enduring final exam week, applying to graduate school, being a victim of crime, having assignments in a number of different classes due on the same day, and breaking up with a romantic partner.

Moving to still younger individuals, researchers have found that the leading life stressors for children overlap to some degree with those of adults and college and university students, but, here again, they largely reflect issues unique to childhood (Hess, Shannon, & Glazier, 2016; Sotardi, 2013). (See photo.) Across various scales, the leading stressors for school-aged children are taking tests, having excessive homework, being made fun of or bullied, feeling left out, getting bad grades, getting in trouble, fighting with family members or friends, experiencing the death or illness of someone close, and doing something embarrassing.

It is worth noting that the kinds of life events that produce stress tend to shift as children develop. As children move from 5 years old to 12 years old, physical-type events (for

example, getting sick) become less stressful, behavioural events (getting into trouble) become more stressful, and psychosocial events (fighting with friends) also become more stressful.

Finally, focus on particular life stressors seems to change from generation to generation (Ryan-Wenger et al., 2005). For example, in the 1990s, awareness about a number of different childhood events, such as experiences about being bullied and experiencing violence in school, became more recognized as stressors of childhood and therefore became prevalent items on children's life stress scales. Similarly, during the 2000s, several other powerful childhood stressors have emerged, such as cyber bullying, terrorism, and concerns over post-earthquake nuclear meltdowns.

Traumatic Events

Life changes are stressful because they disrupt the routines of our lives. **Traumatic events** are more extreme disruptions—unexpected events that have the power to change the way we view the world. The earthquakes and tsunamis in Japan in March 2011, the train disaster in Lac-Mégantic in July 2013, and the COVID-19 pandemic of 2020 are examples of the stress-inducing power of single, cataclysmic events (see photo). Sexual or violent assault can also be traumatizing. Such events can have profound and long-lasting effects. Victims may experience a sense of helplessness, depression, anxiety, numbness, and disorientation (Alpass et al., 2016; Carretta & Burgess, 2013). In some cases, the effects can last for years.

traumatic events unexpected events severe enough to create extreme disruptions.

Joe Raedle/Getty Images

Traumatic events A resident wades in flood waters as he waves to a rescue crew in the wake of Hurricane Harvey, which hit Houston, Texas in August 2017. Major disasters, such as this, can be traumatizing for survivors.

Some victims of extraordinarily traumatic events develop **posttraumatic stress disorder (PTSD)**, a condition characterized by persistent, frightening thoughts or memories of the traumatic events, along with anxiety, depression, and other symptoms. We will discuss this disorder in more detail later in this chapter.

> **posttraumatic stress disorder (PTSD)** an anxiety disorder experienced in response to a major traumatic event, characterized by lingering, persistent, frightening thoughts or memories of the traumatic events, along with anxiety, depression, and other symptoms.

Although traumatic events are usually of short duration, some can be ongoing. Suffering ongoing physical or sexual abuse or living with an alcoholic partner or parent are examples of long-lasting traumatic events. These, too, can leave victims withdrawn and experiencing recurring mental images, anxiety, and depression (Carretta & Burgess, 2013).

Fertnig/Getty Images

Chronic Job Stress **Certain jobs produce chronic stress. For example, having to deal with low wages, unpredictable shifts, and physically demanding work environments can lead to chronic feelings of stress that can influence health and well-being.**

Chronic Negative Situations

A negative situation may become particularly stressful if it continues over a long, perhaps indefinite, period of time (Monroe & Slavich, 2016; Schmidt, Sterlemann, & Muller, 2009). People living in a war zone, for example, confront the fearful possibility of an attack as they go about their daily lives, attending school, shopping, or taking the bus to work. Similarly, people who live in poverty face constant concerns about meeting their basic needs and paying their debts (Freeman & Stansfeld, 2014). An ongoing negative home environment—marked by endless arguments with a spouse or child, for example—may produce considerable stress, and so may enduring workplace problems, such as continually feeling underpaid, unappreciated, bored, or in danger of being fired (Grawitch, Ballard, & Erb,

2015; Son & Peterson, 2016). (See photo.)

Chronic illnesses can also produce much stress over time. Such illnesses may not only cause pain, but also impose limitations and produce feelings of mortality and uncertainty in people's lives. The patients themselves are not the only ones affected by chronic illnesses; their caregivers also experience stress. Thus, parents of children with special needs—whether enduring illnesses, physical handicaps, intellectual disability, or other conditions—often experience stress. So do the growing numbers of adults who must take care of aging parents or spouses. In fact, research indicates that such caregivers often suffer from depression, drink excessively, are sleep deprived, and engage in fewer healthful behaviours, such as exercise (Do, Cohen, & Brown, 2014; Zarit et al., 2017).

The physical environment may also provide chronic stressors. Chronic noise, for example, often leads to tension and upset (Burns et al., 2016; Ferguson et al., 2013). Similarly, chronic overcrowding leads to higher bodily arousal and makes it difficult for people to relax (Hotwani & Tripathi, 2017). Chronic environmental stressors may interact with each other. A noisy roommate, may be both a physical and a social stressor. The roommate's loud music may bombard you and leave you with frequent headaches; at the same time, the tense relationship that develops between the two of you may produce further stress.

Socio-cultural Conditions

Socio-cultural conditions, such as those faced by members of ethnic minority groups who regularly confront prejudice, can be sources of stress (Alamilla et al., 2017). Work by McGill University's Laurence Kirmayer and others clearly shows that minority-group members, including those in Canada's First Nations and Métis populations, face special challenges and stressors as they try to navigate through the dominant culture (Chachamovich et al., 2013; Kirmayer, Sheiner, & Geoffroy, 2016). Foreign workers participating in Canada's temporary foreign worker program, for example, have to adjust to new ways of doing things, learn a new language, and often contend with poverty and the stress of a crowded living situation. In addition, members of minority groups often have to try to balance the demands of two cultures—their own culture and that of the dominant culture in which they live. If they are not proficient in the language or nuances of the dominant culture, they may also experience the stress of isolation and of having limited access to the main channels of communication within the dominant culture (Strauss & McGrath, 2017).

And even when minority-group members achieve success in the dominant culture, another source of stress can emerge as individuals find themselves having to assess the role that prejudice and discrimination may have played in their interactions with the dominant culture. For example, consider Jonathan, an Indigenous Canadian man working in advertising at a large department store. Jonathan's job is to produce advertisements for special sales of fall clothing. His boss, who is Caucasian, doesn't think much of the two ideas Jonathan has proposed and tells him so. In addition to feeling disappointed and perhaps angry about the rejection of his ideas, Jonathan may experience the further stress of wondering whether his boss was reacting to his Indigenous status or to his ideas. The suspicions, confusion, and resulting vigilance experienced by minority-group members as they interact with majority-group members, often referred to as *stereotype threat*, is a very real stressor for minority-group members, but is often invisible to those in the majority group (Schmader, Hall, & Croft, 2015; Spencer, Logel, & Davies, 2016).

Before You Go On

(Answers to Before You Go On may be found online in the Course Resources.)

What Do You Know?

1. What is the difference between an acute stressor and a chronic stressor?
2. What are the four types of stress experiences?
3. Define the three basic types of conflict.
4. What are daily hassles and what is their impact on health?
5. What is the Social Readjustment Rating Scale?

What Do You Think? • What kinds of situations do you find especially stressful? How do they compare with what your friends find stressful? What do variations in the experience of stress tell us about stress and stressors?

Responding to Stress

LEARNING OBJECTIVE 2

Describe the physiological, emotional, and cognitive responses to stress, and explain how individual responses to stress differ.

We have looked at the kinds of experiences that cause stress. Let's turn next to what happens to people when they experience stress. Responses to stress fall into three general types: physiological, emotional, and cognitive. As you might expect, people vary greatly in their responses.

Physiological Responses to Stress

Although what happens in the brain is critical to the stress response, responses to stress affect both the brain and the body. Think about how you come to know that you are under stress. Typically, your breathing and heart rate quicken, you begin to sweat, your mouth gets dry, and your stomach tightens. What's happening is that your brain has perceived a challenge and is sending signals to your body to prepare to meet it. This response to stress involves a brain–body reaction. Sweating, dry mouth, and stomach tightness are some of the immediate physical effects of stress, but these effects are actually indicators of more basic physiological responses. We examine these responses next and illustrate them in **Figure 14.2**.

The Fight-or-Flight Response

You may remember the discussion of physiologist Walter Cannon's theory of emotion in Chapter 11. Cannon was the first theorist to connect the bodily arousal associated with emotional responses to the need to fight or flee. According to Cannon (1932), the fight-or-

flight response is a series of physiological reactions throughout the sympathetic nervous system and the endocrine system that mobilize an organism to either fight or flee an enemy. The process begins in the brain. The brain sends messages to the endocrine glands and bodily organs along two different routes. One is through the sympathetic nervous system, which as you recall is a division of the autonomic nervous system (ANS). The other is through the hypothalamic-pituitary-adrenal (HPA) axis (Daskalakis et al., 2016; Sarafino et al., 2015).

Geoff Howe/The Canadian Press

Under fire **Riot police were in extreme danger, and likely had high levels of cortisol, a stress hormone, in their bloodstream, during the riot following the Vancouver Canucks' loss during the 2011 NHL playoffs.**

When we confront a dangerous situation, within milliseconds the brain sends messages to the sympathetic nervous system, and these nerves directly stimulate organs of the body (the heart and lungs, for example). (See photo.) The nerves also influence organs indirectly by stimulating the adrenal glands (located at the tops of the kidneys), particularly the inner layer of those glands, an area called the *adrenal medulla.* The adrenal medulla, in turn, releases the chemicals epinephrine and norepinephrine (otherwise known as adrenaline and noradrenaline) into the bloodstream, where they are carried to various organs and muscles, further arousing the organism and enabling it to fight or flee. Normally, the biological changes associated with the fight-or-flight response subside around 15 minutes after the threatening situation eases (Sarafino et al., 2015). (See photo.)

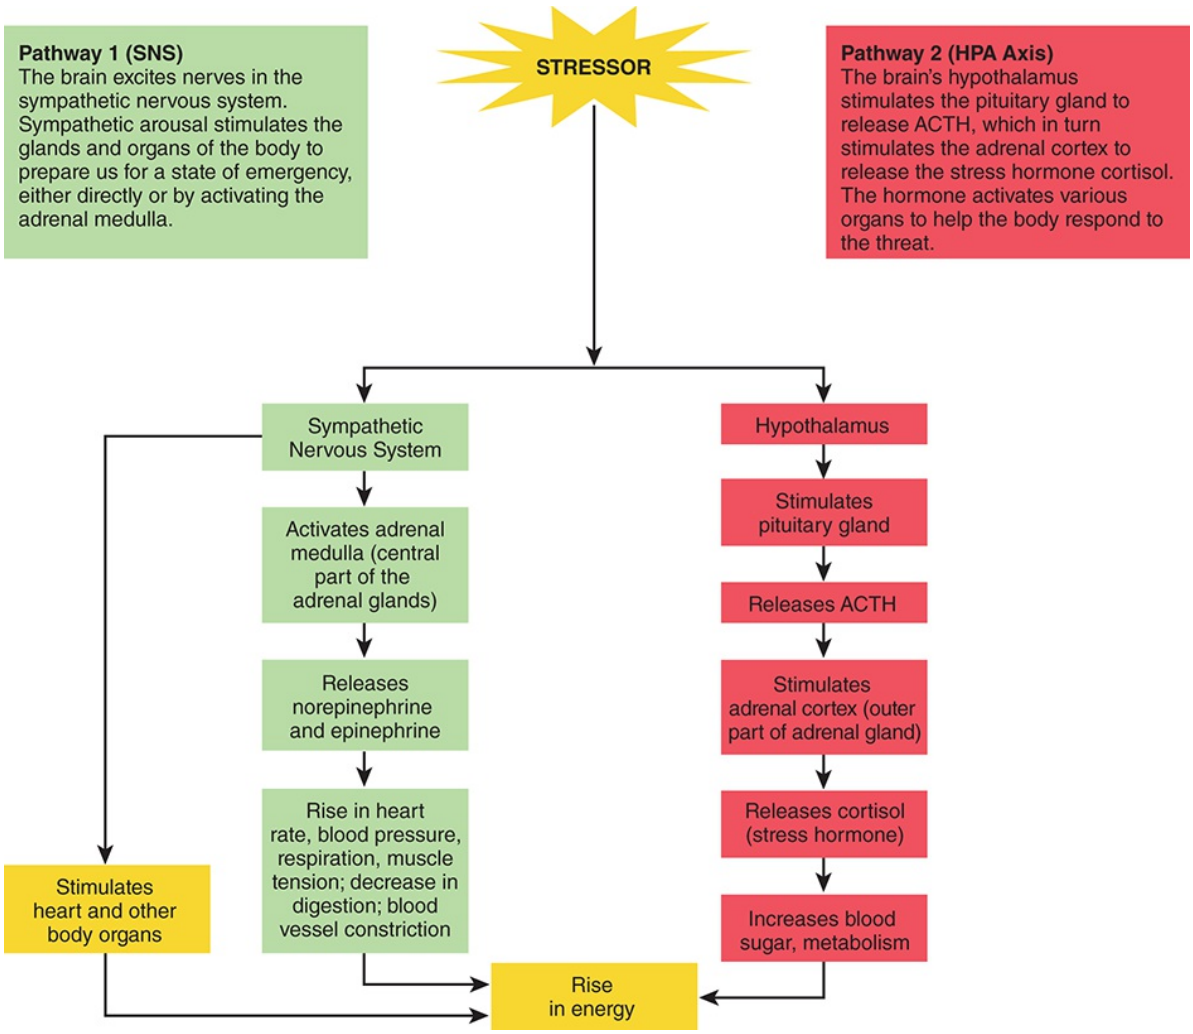


FIGURE 14.2 The physiological response to stress **The brain sends messages to the endocrine glands and bodily organs through the sympathetic nervous system (SNS) pathway and the hypothalamic-pituitary-adrenal (HPA) axis.**

Diverse Images/UIG/Getty Images

Fight-or-flight response **When faced with a dangerous or stressful situation, our brain sends messages to the sympathetic nervous system, which triggers various reactions in the body (such as the release of cortisol to supply energy) to prepare the body for the fight-or-flight response.**

When we are confronted by stressors, the hypothalamus, stimulates the pituitary gland, prompting the gland to release *adrenocorticotropic hormone (ACTH)* into the bloodstream. ACTH travels to the adrenal glands and interacts with their outer covering, an area called the *adrenal cortex*, causing the release of stress hormones called *cortisol*.

Cortisol travels, via the bloodstream or circulatory system, to a range of body organs, where it leads to elevations in blood sugar, which supplies energy to the organism under stress. In this way, cortisol helps prepare individuals who are under stress to engage their fight-or-flight response (Plaford, 2013; Russell & Lightman, 2019).

These two systems (the sympathetic nervous system and the HPA axis), activated in tandem, ensure that the organism is able to mobilize its energy to deal with a crisis, even if it takes a while. As you will see later in the chapter, however, problems can arise if cortisol activity remains high for too long. It can then become harmful, contributing in some cases to high blood pressure, inflammation, anxiety, and depression, among other problems (Do Yup Lee & Choi, 2015; Kendall-Tackett, 2010).

The fight-or-flight response is an early evolutionary adaptation. You can imagine how this kind of reaction might have helped early humans survive. If they suddenly came upon a grizzly bear, they were better able to either overwhelm it or escape in a hurry. But many of the stressors we face today are more subtle and more chronic—homework stress, employment pressures, relationship difficulties, and any number of other conditions. What happens when a stressor is chronic? Hans Selye considered that question in forming his theory of the general adaptation syndrome.

The General Adaptation Syndrome

Hans Selye was an Austrian-born endocrinologist who immigrated to Canada in 1939. He

worked at McGill University and the University of Montreal and is credited with first talking about stress in living creatures (Greenberg, Carr, & Summers, 2002; Selye, 1993, 1956, 1936). In his laboratory, Selye exposed animals to a variety of stressors. No matter what the stressor—mild shock, pain, restraint, heat, cold—he found that the animals displayed the same pattern of response: a consistent pattern that he labelled *stress* (a term he borrowed from engineers, who use it when they discuss forces that affect the structural integrity of the things they build). Selye believed we respond in much the same ways to stress, whatever its source. This insight was particularly important, because it means that, although our responses to different stressors might vary in degree, we are responding in the same basic way to all of them.

Selye also noticed that if stressors continue, the organism's body progresses through three stages of response: alarm, resistance, and finally, exhaustion. He called this three-stage response to stress the **general adaptation syndrome (GAS)** (see **Figure 14.3**).

general adaptation syndrome (GAS) a three-stage response to stress identified by Hans Selye; the stages are alarm, resistance, and exhaustion.

STAGE 1: When an organism is first exposed to a threat, it reacts with *alarm* and becomes aroused physically as it prepares to face the challenge by fighting or fleeing. In short, the first stage of the general adaptation syndrome corresponds to the fight-or-flight response. Because our system is focused on the stressful event or situation and mobilizing us physiologically to deal with it, our resistance to the stressful event (shown by the red line in Figure 14.3) is reduced (see photo). If the stress is too powerful, it could overwhelm us.

STAGE 2: If the threat continues, the organism's body undergoes further changes in an attempt to stabilize itself—a second wave of adaptation that Selye called *resistance*. The organism's level of arousal is elevated, though slightly lower than during the initial alarm phase, as it adjusts to the stressor. If new stressors are introduced during this stage, the body is less able to marshal the energy needed to address them as it is engaged in resisting the previous stress. According to Selye, this makes the body vulnerable to *diseases of adaptation*—health problems, such as high blood pressure, asthma, and illnesses associated with impaired immune function.

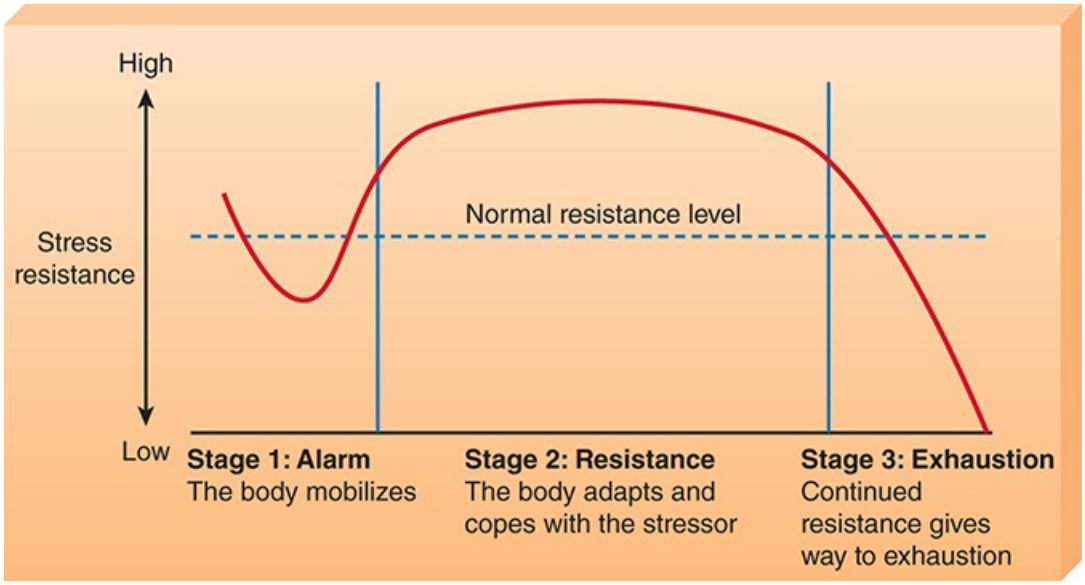

FIGURE 14.3 The general adaptation syndrome Selye proposed that the body's physiological response to prolonged stress has three stages. The red line in this figure shows the level of physiological resistance to a prolonged stressful event.

Darryl Dyck/ZUMA Press/Newscom

The alarm mode can save lives As a wildfire moved closer to Boston Flats, BC, in July 2017, residents moved into an alarm mode, fleeing the fire as quickly as possible.

STAGE 3: If the organism is exposed to the stressor for still longer periods of time, its resistance gradually gives way to the third stage, *exhaustion*. In this stage, the body is depleted of energy and has little ability to resist. If the threat continues, the organism can suffer organ damage or death.

Students who have gone through final exams often have firsthand experience with Selye's

general adaptation syndrome. As the exams approach, most students experience alarm. When they gear up and begin patterns of late-night studying, the students are entering the resistance phase. By the end of the exam period, many students feel as if they are heading toward exhaustion, and, in fact, a number catch colds or develop other illnesses at the end of the school year. If you haven't gone through a final exam period yet, you will soon have a chance to gather your own data on this student experience.

Although the principles of Selye's theory are widely accepted today, some theorists, such as Sonia Lupien at the University of Montreal, have questioned his claim that the stress response is the same no matter what the stressor (Lupien et al., 2007, 2006; Souza-Talarico et al., 2011). Lupien points out that although Selye used many kinds of stressors in his experiments with animals, all were physical—pain, heat, cold, and so forth. As we shall soon see, psychological factors also play an important part in our stress experience.

Emotional Responses to Stress

Bodily arousal is only one dimension of our reaction to stressors. When people feel threatened by an event or situation, they typically experience a change in mood or emotions as well. Let's briefly revisit Ashley, the stressed-out student from the chapter opener. As the stressors in her life mount, Ashley feels increasingly dejected (she wants to curl up in a ball), annoyed (her inquisitive parents are "driving her crazy"), anxious (she had to leave her public speaking class in the middle of a speech), and angry (during an argument with Jason, she called him a jerk).

Note that most of Ashley's emotional responses to stress are negative. This is typical of people under stress. Researchers have found that the more stress a person experiences, the more negative their emotions, especially for individuals who are predisposed to anxiety and depression (Baqutayan, 2015; Eberhart et al., 2011; Lazarus, 2007, 1999, 1993a, 1993b; Ruscio et al., 2015). People who generally live under severe stress tend to be more anxious, depressed, or otherwise upset than those who have relatively stress-free lives. Even within the course of a day, people feel more negative when short-term stressors emerge. Conversely, as perceived daily stressors subside, people's moods take an upward turn (Lacaille et al., 2018).

It was once thought that certain negative emotions—anxiety and depression—were more likely than others to emerge during stress. However, researchers have learned that, in fact, a range of different negative emotions may accompany stress, depending on an individual's personal style and on the stress-inducing situations. The most common emotional reactions include anxiety, fear, and apprehension; dejection and grief; annoyance, anger, and rage; guilt; shame; disgust; and jealousy (Baqutayan, 2015; Lazarus, 2007, 1993a, 1993b). See Positive Psychology 14.1 for a discussion of one way to reduce stress during emotionally heightened situations such as final exams.

Cognitive Responses to Stress

As we noted at the beginning of the chapter, a key feature of stress is how we *appraise* both the challenging situation and our ability to handle that situation. If asked to speak publicly, for example, one person may be excited and pleased at the opportunity, while another may be fearful and anxious (see Your Brain and Behaviour 14.1 later in this chapter).

Sometimes, as in the fear of public speaking, this appraisal is stable—that is, people tend to react consistently to the prospect of speaking before a group. In other situations, however, the appraisal depends on the person's present psychological state. For example, we may appraise a missing car key as much more stressful on the day of a final exam than on a less eventful day.

14.1 Psychology Around Us | Positive Psychology

Exam Stress and Dog Therapy

Most people have experienced exam anxiety at some point in their lives, and university students perhaps more than others are susceptible to anxiety before an important exam. This anxiety can be great or small, but the larger the level of anxiety, the worse your performance can be when actually taking an exam. While there are many techniques for managing exam anxiety, one tactic that has recently come to the fore is the use of therapy dogs, that people can play with and pet to help them relax, before exams.

Studies have shown that exposure to a therapy dog in the hours before an exam can significantly decrease perceived stress (Barker, Barker, McCain, & Schubert, 2016). Other studies show that the effect of a therapy dog session is relatively long lasting (Ward-Griffin et al., 2018) and produces a number of positive effects—including improved affect, perceived social support, and perceived stress levels—for several hours. Recent pilot evaluations of therapy dogs at the universities of Saskatchewan, Regina, and McMaster have shown that having therapy dogs on campus was linked to lower levels of stress and increased relaxation in the majority of the participants in the study (Dell et al., 2015).

Dog therapy sessions are not just beneficial to those getting ready for that all-important exam. Indeed, dog therapy sessions have been shown to lower stress levels, decrease anxiety, and promote feelings of support and well-being for many categories of individuals under stress, including war veterans, first responders, and people dealing with traumatic life changes, such as the death of a spouse or a dire medical diagnosis (Tsai, Friedmann, & Thomas, 2010; Swall et al., 2019; Yount, Olmert, & Lee, 2012).

De-stressing with a friend **Interaction with a friendly canine can reduce general levels of stress and anxiety – especially during the final exam period – for many students.**

Remember Richard Lazarus and his cognitive-mediational theory of emotions, discussed in Chapter 11? Lazarus believed that emotion is aroused by a combination of two elements—an environmental event and personal factors such as a person's motives and beliefs. In fact, much of his early work was focused specifically on stress, and he identified two steps in how we experience stress (see **Figure 14.4**).

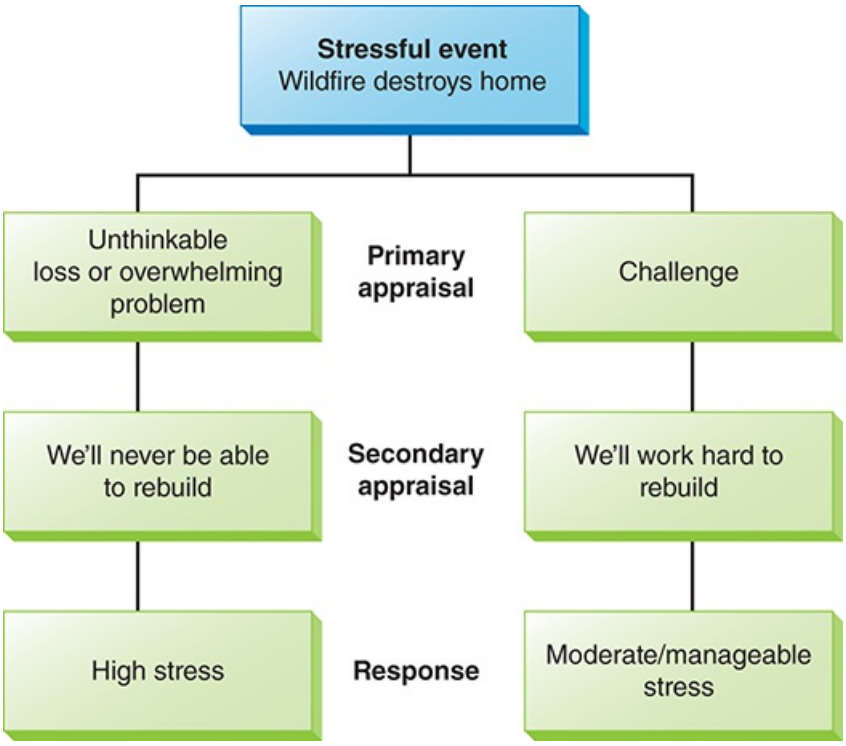

FIGURE 14.4 The cognitive-mediational theory of stress **Our level of stress largely**

depends on how we appraise a threat and evaluate our abilities to cope with it.

In the first step, **primary appraisal**, we examine the stressor and assess how severe it is. We may identify the stressor as a future danger (a threat), a current situation to be confronted and overcome (a challenge), or a loss or harm. The way we appraise the stressor in this first step can have important consequences for how we attempt to deal with it. Ashley, for example, appraised her term paper as a threat to be avoided rather than a challenge to be overcome.

In the second step, we evaluate our own resources and ability to cope with the threat, challenge, or loss. This step is called **secondary appraisal**. Perceiving ourselves as lacking the resources to deal with a problem will elevate its threat level. Conversely, by reminding ourselves of what resources we have, we can quickly decrease the threat level. Consider Ashley's more positive attitude when she musters her resources and quickly produces a few paragraphs of her paper.

primary appraisal appraisal of a stressor to determine how severe it is; the first stage in Richard Lazarus's description of how people experience stress.

secondary appraisal appraisal of one's personal resources and ability to cope with a stressor; the second stage in Richard Lazarus's description of how people experience stress.

One common factor in these appraisals is that the degree to which we feel in control of a situation affects how dangerous or stressful it feels. Perceptions of control (or lack of control) can greatly influence our appraisal of a stressor and, in turn, our experience of stress. Persons who believe that they can exert control over a particular stressor will experience less stress than individuals who feel no such control. A study of residents in a nursing home, for example, found that persons who were given more control over their lives (such as deciding when to attend a movie or where to receive visitors) experienced less overall stress than residents given little control. Residents with control were also twice as likely to still be alive 18 months after the study began (Golub & Langer, 2007; Langer & Rodin, 2004; Rodin & Langer, 1977).

It is important, of course, that our sense of control be realistic. People with life-threatening illnesses such as cancer or heart disease who think that they can control their disease with unproven remedies may feel less stress initially, but they are not likely to be healthier for their efforts. Patients with such illnesses can, however, experience a realistic sense of control (and a lower level of stress) by managing specific aspects of their diseases (seeking out useful medical information, for example), taking part in treatment decisions, controlling some of their emotions, and seeking closer relationships with their loved ones (Doka, 2013; McKinley et al., 2012).

Individual Responses to Stress

It should be clear by now that when it comes down to it, how stressed someone gets in a particular situation often depends on whom we're talking about (see photos). You probably have friends who collapse at the slightest hint of trouble, and other friends who are experts in crisis management. Perhaps you have other friends who just let trouble roll off their

backs without even a suggestion of worry.

Displaying stress Each child displays a different reaction to the first day of school: one seems overwhelmed (left), another frustrated and angry (middle), and the other unfazed (right).

Individuals are unique in many ways. Each of us has a particular biological makeup, a preferred style of interpretation, and a unique cluster of personality traits. In addition, we each operate within a particular social context. These individual differences profoundly influence our physical, emotional, and cognitive responses to stress. Researchers have spent considerable energy examining four areas of individuality and their relationships to stress: *autonomic reactivity*, *explanatory style*, *personality*, and *social support*.

Autonomic Reactivity and Stress

Earlier, we observed that the autonomic nervous system (ANS), particularly the sympathetic nervous system, plays a key role in stress reactions. When a person confronts a stressor, the ANS stimulates organs throughout the body, triggering feelings of physical arousal. As you might expect, people differ in how intensely the ANS responds to stressors. In some, the ANS tends to be highly reactive across various situations and springs into action, even in response to mild stressors. In others, the ANS is less reactive and so less likely to respond even to fairly significant stressors. Such basic differences in *autonomic reactivity* may cause some people to experience stress reactions more often or more intensely than other people, even in the face of identical environmental threats. In turn this difference can influence the development of disorders such as depression and anxiety in children and adults (Dieleman et al., 2016; Hu, Lamers, de Geus, & Penninx, 2016).

To illustrate, let's look at cardiovascular responses to stress, which include blood pressure and heart rate. In a number of studies, researchers have measured the cardiovascular reactions of individuals confronting stressors, such as difficult cognitive or social tasks (Dhabhar, 2014; Phillips, 2016). Across a variety of situations, certain participants repeatedly display high cardiovascular reactivity, while others consistently exhibit low

cardiovascular reactions.

Explanatory Style and Stress

The characteristic manner in which we explain events, our *explanatory style*, can make a difference in how we appraise and respond to stressors. People with generally *optimistic* explanatory styles tend to believe that, despite setbacks, things will improve (Kleiman et al., 2017; Reed, 2016). Those with generally *pessimistic* explanatory styles have a gloomier appraisal—they believe that if things can go wrong, they usually will go wrong (Liu & Bates, 2014).

Imagine two people, each failing to make the first-string college or university soccer team. Both feel disappointed and sad. One says to herself, "I'll never make it. I'm such a dud. I should never have tried out. It was stupid of me to think I was any good at soccer." In contrast, the other individual says, "At least I tried. If I do track in the spring, I can improve my speed and make the team next year. Meanwhile, I'll talk to the coach and find out how I can improve." It is likely that the latter individual—the more optimistic one—will experience less stress than the former.

Research has supported the idea that optimistic and pessimistic explanatory styles influence stress reactions (Carver & Scheier, 2017). When optimistic research participants appraise stressful situations, they are more likely than pessimists to recognize positive features of the situation and to perceive the situation as manageable (Littmen-Ovadia & Nir, 2014). In turn, those with optimistic explanatory styles typically experience lower levels of stress (Birkeland, Blix, Solberg, & Heir, 2017). Similarly, it turns out that optimists are more likely to seek out social support during stressful events and to employ constructive coping techniques, including the use of social networks for social support (Carver, Scheier, & Segerstrom, 2010; Nabi, Prestin, & So, 2013). (We will discuss the importance of social support later in this section.)

Of course, few people are exclusively pessimistic or exclusively optimistic, although they may lean in one direction or other. In fact, some individuals develop an *optimistic brand of pessimism*. These individuals believe that things will go wrong but, at the same time, hope that they won't: "I probably will fail to make the soccer team, but maybe I'll get lucky. If I play my best and the others have problems, I might have a chance." Still other people are *defensive pessimists*. They anticipate negative outcomes largely to help protect themselves from disappointment (del Mar Ferradas et al., 2017; Roy Chowdhury, 2016). Deep down, they hold out hope for the best, and so manage to preserve a degree of optimism.

Personality and Stress

Our personalities often help set the tone for how we appraise and react to stressors (Hengartner, van der Linden, Bohleber, & von Wyl, 2017; Stroud, Sosoo, & Wilson, 2015). People who are generally timid will likely greet a stressor with more alarm than people who are generally bold. Similarly, our ongoing levels of anger, depression, curiosity, and related feelings will influence our stress reactions. Ashley's breakup, for example, appeared to be precipitated by her general tendency to react to stressors by becoming moody and critical.

One personality style that has been studied is the *hardy personality*, sometimes called the

stress-resistant personality (Bartone, 2003; Maddi, 2014; Ouellette & Di Placido, 2001). Individuals with such personalities welcome challenges and are willing to commit themselves and take control in their daily lives. Generally, they greet stressors as opportunities for growth rather than as crises, and perceive stressors as less severe than non-hardy individuals. Not surprisingly, hardy persons also seem to experience fewer and less intense feelings of stress (Abdollahi, Abu Talib, Yaacob, & Ismail, 2015).

At the other end of the stress continuum are people with personality styles that appear to make them more prone to stress. In the late 1950s, two cardiologists, Meyer Friedman and Raymond Rosenman (1959), reported that many of their heart patients seemed to share similar personality traits: they were consistently angry, cynical, hard-driving, impatient, and time conscious. They were also competitive, ambitious, and in a hurry to do many things at once. Friedman and Rosenman claimed that individuals with this personality style, which they labelled **Type A**, interact with the world in a way that produces continual stress (Friedman & Rosenman, 1959; Jamal & Baba, 2003; Smith & Gallo, 2001; Miller, 2000). In contrast, people who display **Type B** personalities are more relaxed, less aggressive, and less worried about time. People with this personality style are thought to experience lower levels of stress. In fact, most people fall between these two extremes, leaning toward one or the other but showing features of both personality patterns.

> **Type A** a personality type characterized by competitiveness, impatience, and anger and hostility.
>
> **Type B** a personality type that is less aggressive, more relaxed, and less hostile than Type A.

Researchers later suggested there might be a third personality pattern, **Type C**. People with this personality type are pleasant and peace loving, but have a hard time expressing or acknowledging negative feelings (Temoshok, 2003; Temoshok et al., 2008). Although their positive attitudes might be thought to protect them from stress, persons with Type C behaviour patterns are actually particularly vulnerable. When angry, Type C personalities tend to turn the anger inward. They also tend to take losses and relationship problems particularly hard. Recently researchers have identified a **Type D** personality pattern characterized by negative affectivity such as worry or gloominess and social inhibition. The "D" stands for distressed, and this personality pattern seems to have a number of health implications (Schoormans et al., 2017; van den Tooren & Rutte, 2016). We will talk more about Type A, Type B, Type C, and Type D personality types when we discuss the relationship between stress and health later in the chapter.

> **Type C** a personality type characterized by difficulty in expressing or acknowledging negative feelings.
>
> **Type D** a personality type characterized by negative affectivity such as worry or gloominess and social inhibition.

Social Support and Stress

As we think back to Ashley's struggle at the beginning of the chapter, notice that she seems

to be going through her difficulties alone, without much social support. She does not feel free to turn to family members, and she does not appear to have close friends in whom she can confide. In fact, family and social relationships seem to add to her experience of stress. Would Ashley have felt better if she could have turned to family members or friends for support? The answer is yes, not only for humans but also for our closest primate relatives, chimpanzees, according to numerous studies and observations (Levens, Elrahal, & Sagui, 2016; Stein & Smith, 2015; Taylor, 2011; Wittig et al., 2016).

Richard Heathcote/Getty Images

Social support can make the difference A Korean golfer comforts her playing partner as the latter is sizing up a difficult putt on the 18th green of the Women's World Cup of Golf in 2008. The partner went on to sink the putt.

Social relationships can be paradoxical. On the one hand, as in Ashley's case, negative interactions with or a lack of social support from relatives and friends can be sources of significant stress (Taylor, 2011; Wickham, Taylor, Shevlin, & Bentall, 2014). On the other hand, studies have resoundingly indicated that social relationships and support, in person or via online social networks, help prevent or reduce stress reactions (see Psychology Around Us 14.1) (Dunkley, Solomon-Krakus, & Moroz, 2016; Frison & Eggermont, 2015).

The positive impact of social support on stress was first revealed in animal studies. In a classic study, twin goats were subjected to a stressful conditioning task. One goat worked in isolation and the other worked in the presence of its mother. The goat working in isolation reacted with greater anxiety and stress than did its twin (Liddell, 1950). In another classic study, a group of mice had to "share" a common feeding place, which created a persistent state of territorial conflict (Henry & Cassel, 1969). In one condition, the mice in the group were strangers, while in the other the mice were from the same litter. The former group showed more signs of stress than did the latter. These classic studies have been followed up with studies in a variety of other animals and the results resoundingly support the role of social support in mitigating stress (Beery & Kaufer, 2015; Feder, 2019; Takahashi, Flanigan, McEwen, & Russo, 2018).

Studies of humans have revealed a similar role for social support in stress reactions (Levens et al., 2016; Taylor, 2011). It has been found, for example, that when faced with various job stressors, ranging from work overload to job conflict, workers who can rely on their supervisors, co-workers, and spouses for emotional and practical support often experience less distress than workers without such support (Carpenter et al., 2015; Woodhead, Northrop, & Edelstein, 2016). Other studies suggest that having an intimate, confiding relationship with someone, whether a spouse, close friend, or other individual, provides the strongest kind of social support (Olpin & Hesson, 2013). (See photo.)

Why do people who have strong social support seem to experience less stress? Researchers are not sure. Such support may increase people's self-confidence or self-esteem as they confront stressors. It may provide individuals under stress with a greater sense of control or greater optimism that everything will turn out well. Alternatively, social feedback may change people's perspectives as they face stressors, alter their perceptions of threat, or reduce their appraisal of a stressor's importance. Finally, it may be that the reassuring presence of close friends or relatives helps to reduce the kinds of bodily arousal and negative emotions that normally feed stress reactions (Levens et al., 2016; Taylor, 2011).

Before You Go On

(Answers to Before You Go On may be found online in the Course Resources.)

What Do You Know?

6. How do the sympathetic nervous system and hypothalamic-pituitary-adrenal pathways influence our experience of stress?

7. What happens in each stage of the general adaptation syndrome?

8. What is the difference between primary appraisal and secondary appraisal?

9. How does autonomic reactivity affect how different people experience stress?

10. What are the characteristics of the hardy personality type?

What Do You Think? • Can you think of any advantages to having a Type A personality? A Type C personality? Can you think of any disadvantages to having a Type B or a type D personality?

Coping with Stress

LEARNING OBJECTIVE 3

Discuss and evaluate several ways in which people cope with stress.

We have seen that a number of individual differences contribute to how stressed we become. Once we feel stressed, we also differ in our efforts to manage the situation. What do you do when you feel stressed? If you feel overloaded or overburdened, do you lie in bed

worrying about all that you have to do, unable to get started, or do you start making lists and timetables? If you are in a traffic jam, do you pound the steering wheel, or do you instead try to find an interesting radio station or play your favourite song? Faced with the worrying prospect of a chemistry midterm, do you call a friend to study or light a cigarette?

14.2 Indigenous Experiences

Coping with Stress

Most residential school survivors who spoke to the Truth and Reconciliation Commission spoke of neglect, sexual and physical abuse, trauma, despair, illness, crippling fear, and overwhelming loneliness and homesickness. However, some also spoke of "qualified benefits" such as forming important and sustaining friendships, skills acquired, field trips, movies, access to books and comics and, for a very few, escape from even worse home environments. Survivors especially enjoyed the times they got to be outdoors, reporting, "We go sliding. We play all kinds of games on the lake and, oh, we'll just have fun" (McNeely, 2010, p. 187) or, "When we were in the woods, we felt free, or we were down on the beach by the water, collecting food that we were used to eating" (Charleson, 2010, p. 187). As well, although not common, some residential schools provided students with chances to engage in organized sports or other forms of recreational activity. Many survivors given these opportunities reported that these extracurricular activities provided them with a refuge from the degradation, fear, and anxiety that characterized their day-to-day existence. For many, these experiences in the gym or on the field provided them with a much needed sense of accomplishment, "And there was times when I was called dumb and stupid and there were times when I felt dumb and stupid. But put me in a gym, there was not too many people better than I am" (Andrew, 2011, p. 189). For others, activity simply provided a means of temporary escape, "I was quite athletic, and basically, that's what kept me alive. That's what kept me going was the sports." (Kimball, 2011, p. 189) and, "One of the good things that I would do to try and get out of just the abuse was try to, I would join track meet, try and be, and I was quite athletic in boarding school" (Shingoose, 2010, p. 189). However, for others the abuse from the school simply extended to the sports arena, "When we were losing, we were getting beaten with a ruler. We always had to win. We didn't know how to lose. It was always, win, win" (Papatie, 2012, p. 190). But even for those for whom the gym or team offered solace, it was not enough. One student athlete, who later played professional hockey said, "I didn't want to be an athlete, I didn't want to be a hockey player, I didn't want to be anything. All I wanted was my parents" (Sasakamoose, 2012, p. 193).

Matteo Omied/Alamy Stock Photo

Team sports **Many survivors reported that during their time in residential schools, team sports and the ability to be outdoors provided a welcome respite from many of the hardships they experienced in their day-to-day lives.**

Critical Thinking Questions

What type of coping strategies are referred to in this box? Which do you think was most effective and why?

What role, if any, would cognitive appraisal play in the situations discussed in this box?

How might the role of exercise become an additional stressor, rather than a coping mechanism, in the situations described in the box?

Our efforts to manage, reduce, or tolerate stress are called **coping**. Although most people use this term to convey constructive efforts ("I'm coping with the situation"), a coping response may be either adaptive or maladaptive in a given situation (Folkman & Moskowitz, 2004; Kleinke, 2007). For a person faced with failing grades, for example, going out and partying or spending a lot of time video gaming are less adaptive coping responses than spending extra time studying. Each of us has preferred styles of coping that we tend to apply across various situations (Aldwin, 2007; Carver & Scheier, 1994, 2003; Folkman & Moskowitz, 2004). A person may use different coping responses in different situations, however, and some *coping-flexible* individuals are more able than others to depart from their preferred coping styles to meet the demands at hand. Let's look at some of the more common coping styles (see Indigenous Experiences 14.2).

coping efforts to manage, reduce, or tolerate stress.

Humour

In a 1998 film, Robin Williams donned a white coat and a red clown nose and took a new

brand of medicine to movie theatres around the world. He was playing real-life physician Patch Adams, who believes that the medical community has failed to embrace the use of laughter and humour to aid in health and healing (Marsh, 2008). (See photo.) While this may be a feel-good sentiment, is there actual support for the notion that laughter is the best medicine? Research results from medicine and psychology are mixed in their support of a laughter–health link (Booth-Butterfield & Wanzer, 2017). For example, humorous film watching where viewers laughed has been correlated to decreases in stress and improvements in their immune system activity (Bennett, 1998; Kantha, 2015; Monahan, 2015). On the basis of such supportive findings, psychologists have offered various explanations for how laughter might improve health (Gonot-Schoupinsky & Garip, 2018; Savage, Lujan, Thipparthi, & DiCarlo, 2017). Some of these explanations suggest that there is a direct link between laughter and health. One proposal, for example, holds that laughter may increase blood flow, thereby reducing blood pressure (Dolgoff-Kaspar et al., 2012). Another proposal argues that 100 laughs can provide an aerobic workout equal to 15 minutes on an exercise bike (Brickey, 2005). Still other scientists suggest that the link between laughter and health is an indirect one. One popular proposal, for example, supported by research conducted by Elsa Marziali at the University of Toronto, suggests that humour results in greater social support, thereby aiding health, and that humour may help heal by bringing down a person's stress level (Marziali, McDonald, & Donahue, 2008).

Jessica Teft/Keystone

A different approach The real Patch Adams, physician and clown, talks here to the sister of a hospitalized child.

Other research suggests that support for the humour–health link is less clear and perhaps more questionable than first thought. Some studies on this subject have failed to support the link (Cho & Oh, 2011). Clearer verdicts on the strength of this relationship and on the theories that seek to explain it await the results of current and future research. In the meantime, there is nothing in the literature to suggest laughter is bad for one's health, and many health and humour experts have offered tips on how to increase one's daily quota of

good humour. They suggest, for example, browsing through the humour section of a local bookstore; keeping a humour journal filled with funny newspaper headlines, bumper stickers, and notes about humorous events; and reading cartoons daily, making sure to save and post the ones that tickle your funny bone the most (Savage, Lujan, Thipparthi, & DiCarlo, 2017).

Meditation

Meditation is a technique designed to turn one's consciousness away from the outer world, toward inner cues and awareness, ignoring all stressors (Butler, 2011; Van Dam et al., 2018). The technique typically involves going to a quiet place, assuming either a specific body position or simply a comfortable position, controlling one's breathing, limiting one's outward attention, and forming internal images (see photo). The result of such efforts is an altered state of consciousness, accompanied by deeply relaxing and pleasant feelings, all of which are associated with lower levels of stress (Gamaiunova, Brandt, Bondolfi, & Kliegel, 2019; Gotink et al., 2016; Hoge et al., 2018).

meditation technique designed to turn one's consciousness away from the outer world toward one's inner cues and awareness.

©iStockphoto.com/AnanthaVardhan

Meditation and mental well-being **Various types of meditation go back long before it became of interest to psychologists and the focus of research.**

Meditation is an ancient practice that can be traced through the history of all the world's

major religions. Pictorial evidence of what appears to be people in meditative postures have been found on ancient walls dating back to between 5,000 and 3,500 years BCE (Possehl, 2003). Perhaps the best-known practices derive from the yoga traditions of the Hindu religion and from the Zen traditions of Buddhism. Psychologists have become quite interested in the features of various meditative techniques. These techniques all seem to include versions of self-regulation practices that involve training attention and awareness to bring our mental processes under greater voluntary control (Dahl, Lutz, & Davidson, 2015). When practised, they seem to be able to positively influence mental wellbeing and/or impact specific capacities such as calm, clarity, and concentration (Shaner, Kelly, Rockwell, & Curtis, 2017).

Two major meditation techniques seem to use opposite approaches. In *opening-up* approaches, meditators seek to clear their mind to receive new experiences. One opening-up technique is to imagine oneself as another person; a related opening-up technique involves the performance of a common task in a slightly different way, designed to call better attention to one's daily routine. In the other kind of meditation approach, *concentrative meditation*, people actively concentrate on an object, word, phrase, or idea, called a *mantra*. Concentrating upon or repeating a mantra serves to calm and focus the mind and, perhaps, clear your mind completely.

One of meditation's greatest secular appeals is that it can help people relax (Brown et al., 2010; Scotland-Coogan & Davis, 2016). In fact, studies have shown that people in meditative states experience brainwave patterns that are similar to the relaxation phase many individuals experience before falling asleep.) (Kaur & Singh, 2015). More recent work by Christina Lavalee at Laurentian University suggests that this sleeplike type of relaxation effect may be most pronounced in novice meditators, and that experienced meditators may not show the same pattern but rather seem to relax without becoming sleepy while meditating (Lavallee, Koren, & Persinger, 2011).

Researchers have found that meditation also can lower respiration, heart rate, blood pressure, and muscle tension. Because of its positive impact on physical functioning, it has been used to help treat pain, asthma, high blood pressure, heart problems, skin disorders, diabetes, and infections, and can reduce stress and anxiety (Black & Slavich, 2016; Gregoski et al., 2011; Hilton et al., 2017; la Cour & Petersen, 2015). One form of meditation that has been applied in particular to patients suffering from severe pain is *mindfulness meditation* (Labbé, 2011; Zeidan & Vago, 2016). Here, meditators pay attention to the feelings, thoughts, and sensations that are flowing through their minds during meditation, but they do so with detachment and without judgment. By being mindful but not judgmental of their feelings and thoughts, including feelings of pain, the individuals are less inclined to label or fixate on them and, in turn, are less likely to react negatively to them. Being mindful or being in the moment can help us look past distractors and focus on the tasks immediately at hand. For example, in a recent study of psychology students, meditation before listening to a lecture improved test performance after the lecture (Ramsburg & Youmans, 2014). Meditation has also been shown to reduce stress and improve mood among post-secondary students (Spadaro & Hunker, 2016). It may be worth giving it a try!

Lashing Out

As stressors pile up, people often say that they feel "as if they're going to explode." Thus, it

is not surprising that some individuals do in fact explode—psychologically or physically. They react to stress by lashing out at other people with angry words or behaviours (see Psychology Around Us 14.2). Around one-quarter of adults report such reactions (Williams & Nida, 2011).

Lashing out often occurs after a series of stressors has taken place. The particular event that triggers an aggressive outburst may seem relatively mild in itself, but for the individual under siege, it is the last straw. Recall how Ashley, the beleaguered student in our case opener, blew up at her boyfriend, Jason, during a phone conversation, calling him names and hanging up on him. Jason's crime? He had refused to let her off the phone. Ordinarily, this teasing might not have elicited such a strong reaction. But Ashley was feeling pressure from her boss, her parents, and the demands of her schoolwork. Ashley's explosive reaction isn't surprising when we consider the cumulative impact of these multiple stressors.

Everyone is capable of lashing out at others in the face of stress. For most people, it is an occasional and temporary reaction, performed before they have time to think about things and decide how to act more constructively. For some people, however, lashing out is a characteristic mode of coping. Recall that Ashley had been in the habit of lashing out at Jason. These outbursts were, in fact, a key reason that Jason decided to break up with her.

Angry outbursts, although sometimes understandable, are not typically a constructive way of dealing with stress. Such outbursts may harm relationships, produce psychological or physical damage, and lead to additional stress. Theorists and clinicians once believed that expressions of anger were cathartic, or cleansing—that is, if people expressed their anger and "got their frustrations out of their system," they would feel better and be able to move forward constructively. It turns out, however, that excessive or continuous expressions of anger usually cause further outbursts (Tavris, 2003, 1989). In one study, experimenters induced anger in participants and then directed one group of angry participants to hit a punching bag and the other group of angry individuals to sit quietly (Bushman, Baumeister, & Stack, 1999). Later in the experiment, the "punching bag" participants were found to behave much more aggressively than the "sit quiet" individuals. Similarly, angry participants in another study were attracted to violent video games (Bushman & Whitaker, 2010).

14.2 Psychology Around Us

Cursed Response

Want a quick relief from stress? Angry outbursts may not work, but apparently shouting out your favourite curse word can help. Richard Stephens and his research group at Keele University in England had college students put their arms in a bucket of ice water for as long as they could (Stephens, Atkins, & Kingston, 2009). Some of the participants were instructed to shout out curse words of their choosing while holding their arms in the water; others shouted out neutral words only. Which participants do you think were better able to keep their arms immersed in the ice water? That's right: the swearers. In fact, they kept their arms in the water almost a minute longer than the students who repeated neutral words again and again. The effect was strongest for people with lower daily swearing frequencies who do not swear very often (Stephens

& Umland, 2011). Why does swearing help? The experimenters theorized that it triggers our fight-or-flight responses, which help us deal with immediate stress and negate the link between fear of pain and pain perception. But be forewarned (or relieved)—swearing has a much greater coping and pain-reduction effect for occasional swearers than for habitual swearers.

In the long term, lashing out can harm or destroy a person's social support network, as in the example of Ashley and Jason. As mentioned earlier, social support is a primary defence against stress (see Practically Speaking 14.1). By driving away those who could help with stress-related problems, such as anxiety and depression, a person will likely make those problems worse. Perhaps one way to avoid harm to your social network would be to see if you can find one of the anger room businesses that are popping up (see photo). For a price, they provide people with opportunities to put on protective clothing and smash a bunch of random or personally chosen objects with a bat or a hammer.

Mirrorpix/Splash News Newscom

Anger room **Anger rooms or rage rooms are popping up in many cities. While some research on venting suggests it may make things worse, the fact that anger and rage room businesses seem to be thriving suggests that more research may be needed.**

Venting one's anger online is a more contemporary method of possible stress reduction. We don't know yet what the long-term effects of this behaviour are, but individuals who post negative feelings online report a reduction in perceived stress (Wendorf & Yang, 2015). This is also true for smart phone use. While excessive smart phone use can be correlated to an increase in perceived stress by the user, those who use their smart phones to communicate how they are feeling also report a reduction in stress (Karsay, Schmuck, Matthes, & Stevic, 2019).

Self-Defence

In some instances, people run away from—that is, physically leave—stressors through such

actions as dropping a difficult class, changing jobs, or ending a troubled relationship. More commonly, people try to make a "psychological getaway." Considering a complex detailed scholarship application may cause some students to decide not to complete the application and think "they probably don't give out very many of the awards." The student's behaviour in this story is an example of *reaction formation*—saying or doing the opposite of what one actually believes—one of Freud's defence mechanisms.

14.1 Practically Speaking

How Can You Manage Stress?

Europics/Newscom

Mass relaxation **A group of mostly white-collar workers in Changsha, China, receive stress relief training to help them learn to relax and survive the new fast-paced work environment.**

Stress is often unavoidable. The traffic jams, life changes, and occasional natural disasters that create stress are not going to miraculously disappear. The issue, then, is how to handle stress. Is there a way to lessen its impact so that cortisol levels, blood pressure, and the like do not soar? The answer, according to many psychologists and studies, is yes (Folkman & Moskowitz, 2004). As this chapter has already begun to suggest, there are quite a few things you can do the next time you anticipate or begin to feel the heart-pounding symptoms of stress.

Exercise, Meditation, and Relaxation

One of the best ways to manage physiological responses to stress is to exercise (Fetzner & Asmundson, 2015; Riley & Park, 2015). In fact, it appears that people who exercise regularly reap not only physical benefits, such as lowering the activity of stress hormones (Beserra et al., 2018; Kennedy et al., 2017), but also psychological benefits, such as increased self-confidence. Similarly, research indicates that some of

those who learn to quiet their thoughts and relax their muscles through meditation and relaxation training experience reductions in stress hormone activity, blood pressure, and anxiety levels (Cardoso, Souza, & Camano, 2009; Stetter & Kupper, 2002).

Social Support

Seeking the support of others, whether in the form of assistance or a sympathetic ear, is another way to ease the effects of stress. Simply knowing that friends or family will be available when needed is a form of social support (Engert et al., 2017; Sippel et al., 2015; Stein & Smith, 2015). It appears that social support helps ease the effects of stress in at least two ways—by helping to reduce the actual number and impact of threatening situations, and by providing practical, problem-focused assistance when stress does occur.

Self-Disclosure

Self-disclosure, the sharing of emotions and experiences with others in person or online, can also help people deal with stress. Up to a point, self-disclosure serves to release stress—consider the phrase "getting things off my chest"—but it is more than simply the venting of emotion. It helps people to channel emotions into a cohesive narrative, making stressors easier to process and deal with (Zhang, 2017; Zhang & Fu, 2020). In addition, by putting fearful, angry, or uncomfortable feelings into language and discussing them with other people, individuals are forced to think about and perhaps better address those feelings. Of course, the effectiveness of self-disclosure is tied to the ability of others to understand the problems a person is going through. Sexual assault victims or former prisoners of war, for example, may discover that certain relatives or friends simply cannot comprehend what they are going through. In such cases, the feedback they receive may need to be facilitated by a therapist to avoid causing more pain to the person who has experienced the trauma (Stein, Lahav, & Solomon, 2017).

Although everyone reacts to stressors with defensive behaviours on occasion, some people use such behaviours regularly. In fact, some people display what theorists describe as a *repressive coping style* (Erskine et al., 2016). They consistently deny negative feelings and discomfort and try to push such emotions out of awareness.

Is the use of defence mechanisms—whether occasional or continual—a helpful way to cope with stress? Sometimes, it probably is. We can all think of instances when it would be best to simply put something out of our mind, particularly if we don't have any control over the outcome (for example, waiting for our grade on a recent exam). Interestingly, this style of coping is used more as people get older, often to the benefit of their psychological well-being (Erskine et al., 2016) In other instances, however, defensive coping is not constructive. After all, while we spend our time defending and avoiding, the problem typically continues. The conflict with a roommate, the course paper that needs writing, and the medical problem that needs attention continue as stressors, and may even intensify.

It is also worth noting that defensive coping as a way to reduce stress can be difficult to achieve. In a classic study by Brown and colleagues (1996) they found that participants with a repressive coping style reported feeling less stress than other participants did when watching a disturbing movie but their autonomic responses were actually higher (for example, their heart rates and blood pressure were higher throughout the film). It may be that repressive coping behaviours *mask* stress rather than eliminate it. Or perhaps the higher autonomic activity associated with repressive coping indicates that such repression requires considerable physical effort. Either way, it is not surprising that people with this coping style have been found to experience more medical problems than do people who use other coping styles (Howard, Myers, & Hughes, 2017; Mund & Mitte, 2012; Myers, 2010).

Self-Indulgence

Many individuals use self-indulgent strategies, such as overeating, smoking cigarettes, and consuming drugs and alcohol, to cope with stress (Sirois & Pychyl, 2016). (See photo.) Ashley went partying with her friends, for example, to deal with the stress created by her paper-writing assignment. Such strategies may help people feel better in the short term, but in most instances they fail to change the challenge at hand and so have little long-term benefit. In fact, such responses are often associated with poor adjustment and depression and anxiety (Cooper et al., 2016; Folkman & Moskowitz, 2004; Moitra, Christopher, Anderson, & Stein, 2015).

shurkin_son/Shutterstock.com

Food and stress **Eating treats and comfort foods are less optimal ways of responding to stress.**

If the problem at hand is transient and simple—recovering from a drive home in a blinding snowstorm, for example—the self-indulgence of having a bowl of ice cream or a beer may indeed help a stressed person to calm down. If, however, the problem is more complex—such as a term paper due next week—self-indulgence is unlikely to be an effective coping strategy. Eating, drinking, shopping, watching television, or surfing the Internet will not make the problem go away. In fact, it may produce still greater pressure and higher stress:

while one indulges, the paper's due date keeps getting closer. Moreover, certain self-indulgent strategies, such as cigarette smoking, excessive alcohol consumption, drug use, and extreme overeating, have serious health effects (Mauro, Canham, Martins, & Spira, 2015; Tryon, DeCant, & Laugero, 2013; Zvauya et al., 2017).

Constructive Strategies

It is possible, of course, to cope with stress constructively rather than lashing out at others or engaging in self-defence or self-indulgence. Psychologists Richard Lazarus and Susan Folkman (1984) suggested the use of the terms *problem-focused coping* and *emotion-focused coping* to distinguish between two kinds of constructive strategies. Which of these strategies we are likely to use depends in part on the nature of the problem. For example, we could try to hit the highway at 4:00 a.m. as a way of dealing with morning traffic, but it is probably more practical to learn how to react calmly and philosophically to rush-hour tie-ups. Conversely, when a tornado watch is posted, figuring out how to calm down may not be as fruitful as deciding whether to head for the cellar or for higher ground.

In **problem-focused coping**, the person's efforts are aimed at dealing directly with the stressor in some way. For example, the late-to-work Ashley might ask her boss to assign her to a different work shift so that she has more time to get to work, or she might look for a new job closer to campus. She might devise a plan to buy a car so that she can save time travelling to work, or she might decide that her earlier solution of jogging to work is worth continuing. In any case, by being proactive and conscientious in dealing directly with the stressor, she can begin to reduce its effects (Bartley & Roesch, 2011; Chao, 2011).

> **problem-focused coping** coping strategies focused on dealing directly with the stressor, such as by changing the stressor in some way.

But what about the noisy 2-year-old next door who keeps interrupting your efforts to relax in the backyard? Or the grief we experience resulting from the death of a loved one? These are not stressors that readily yield to a problem-focused approach. When we can exert little control over stressors, we may instead try to change how we feel toward the stressors, thus limiting their negative effects—an approach Lazarus and Folkman call **emotion-focused coping**.

> **emotion-focused coping** coping strategies focused on changing one's feelings about the stressor.

In some cases, emotion-focused coping may involve *cognitive reappraisal*—finding a way to reinterpret the negative aspects of an uncontrollable situation so that they are less upsetting (Skinner & Zimmer-Gembeck, 2016; Troy, Wilhelm, Shallcross, & Mauss, 2010; Troy, Shallcross, & Mauss, 2013). People who are trying to come to terms with the death of a loved one or with some other catastrophic loss often look for ways to find positive meaning or purpose in their loss (Folkman & Moskowitz, 2004). Similarly, people may reinterpret threatening situations as challenges or tests, rather than catastrophes. The loss of a job, for example, might be viewed as a new beginning or new opportunity (Folkman & Moskowitz, 2000a, 2000b).

Changing how we think or feel about a stressor can also be a useful tactic for less traumatic stressors, such as tests and traffic jams. Rather than becoming increasingly upset over a traffic jam, for example, you may be able to shrug it off—saying, in effect, "It won't be great if I'm late, but I'll survive."

Before You Go On

(Answers to Before You Go On may be found online in the Course Resources.)

What Do You Know?

11. What are the main benefits of altering consciousness through meditation?

12. How can lashing out negatively affect our management of stressors?

13. What is a repressive coping style?

14. Identify and describe two forms of constructive coping.

What Do You Think? • Do you tend to use constructive coping strategies, or do your responses tend to be more maladaptive? Do you adapt your coping style to the situation, or do you tend to use the same style across many different situations? How could you improve your coping style?

Stress and Health

LEARNING OBJECTIVE 4

Explain how stress can cause physical illness, and discuss situations in which stress may be beneficial.

We have seen that stress has a profound effect on bodily functioning. Thus, it should come as no surprise that researchers have found strong relationships between stress and health—or, more accurately, between stress and illness (Groer, Meagher, & Kendall-Tackett, 2010). Scientists' appreciation of this relationship unfolded slowly. Back in the 1930s and 1940s, researchers began to recognize that certain medical illnesses are caused by an interaction of psychological factors (particularly stress-related factors) and biological factors, rather than by biological factors alone. These special illnesses were given the label *psychosomatic* or *psychophysiological diseases.* By the 1960s, a number of medical illnesses were considered psychosomatic diseases. Among the most prominent were ulcers, asthma, tension and migraine headaches, and hypertension (Ramadan, 2000; Rice, 2012; Murison, 2001; Sriram & Silverman, 1998). Although peptic ulcers have since been shown to be bacterial in nature (Marshall, 1994), stress is known to weaken the immune response and thereby increase vulnerability to the development of ulcers (Segerstrom & Miller, 2004).

Maverick/Dreamstime/GetStock.com

Road warrior **Stressful situations such as driving can contribute to a host of medical illnesses.**

As the list of psychosomatic diseases grew, medical researchers began to suspect that stress might, in fact, be at work in a wide range of medical illnesses, not just in a special few (see Psychology@Work video on Occupational Health and Safety). Their suspicions changed to near certainty when studies revealed that stress often contributes to coronary heart disease (the second-leading cause of death, after cancer, in Canada). Researchers continue to investigate how stress is connected to various illnesses, as well as how stress brings about its effects on body systems (see photo).

Coronary Heart Disease

Coronary heart disease involves a blocking of the coronary arteries—the blood vessels that surround the heart and are responsible for carrying oxygen to the heart muscle. The term actually refers to several problems, including blockage of the coronary arteries and *myocardial infarction* ("heart attack"). Together, such problems are the second-leading cause of death after cancer in men and women over the age of 45 in Canada, accounting for close to 50,000 or 20 percent of the deaths each year (Statistics Canada, 2017). Research has shown that most cases of coronary heart disease are related to an interaction of psychological factors, such as job stress, and physiological factors, such as high cholesterol, obesity, hypertension, smoking, and lack of exercise (Bekkouche et al., 2011; Kendall-Tackett, 2010; Statistics Canada, 2017).

14.1 Your Brain and Behaviour

Stressing Out when Speaking in Public

If you are like most people, you feel stressed out when you have to give a speech in

public. What is happening in the brain while you are feeling this pressure? Although you are not in physical danger, your brain is responding to the presence of an audience as if you were. Brain signals activate the sympathetic nervous system (Selye's alarm stage)—resulting in increased heart rate, sweaty palms, and a dry mouth. In the brainstem, the locus coeruleus increases arousal by changing activity in its widespread projections throughout the brain. The amygdala and cortex process sensory stimuli that in turn activate stress systems. The hypothalamus sends signals to the pituitary gland to release a hormone that stimulates the adrenal glands (located on top of your kidneys) to release cortisol, the main stress hormone. This hormone helps to mobilize energy stores so that you can cope with the stressor. Finally, the hippocampus and prefrontal cortex recognize elevated levels of cortisol and send inhibitory signals to the hypothalamus to shut down the stress response. How can you deal with this? Jeremy Jamieson has a solution called reappraisal. Jamieson and his colleagues taught stressed students how to view the physiological experience of anticipatory stress prior to public speaking in positive terms and that helped them to feel less stressed and to perform better when they stood up and spoke in public (Jamieson, 2013; Jamieson et al., 2016; Jamieson, Mendea, & Nock, 2012).

Questions

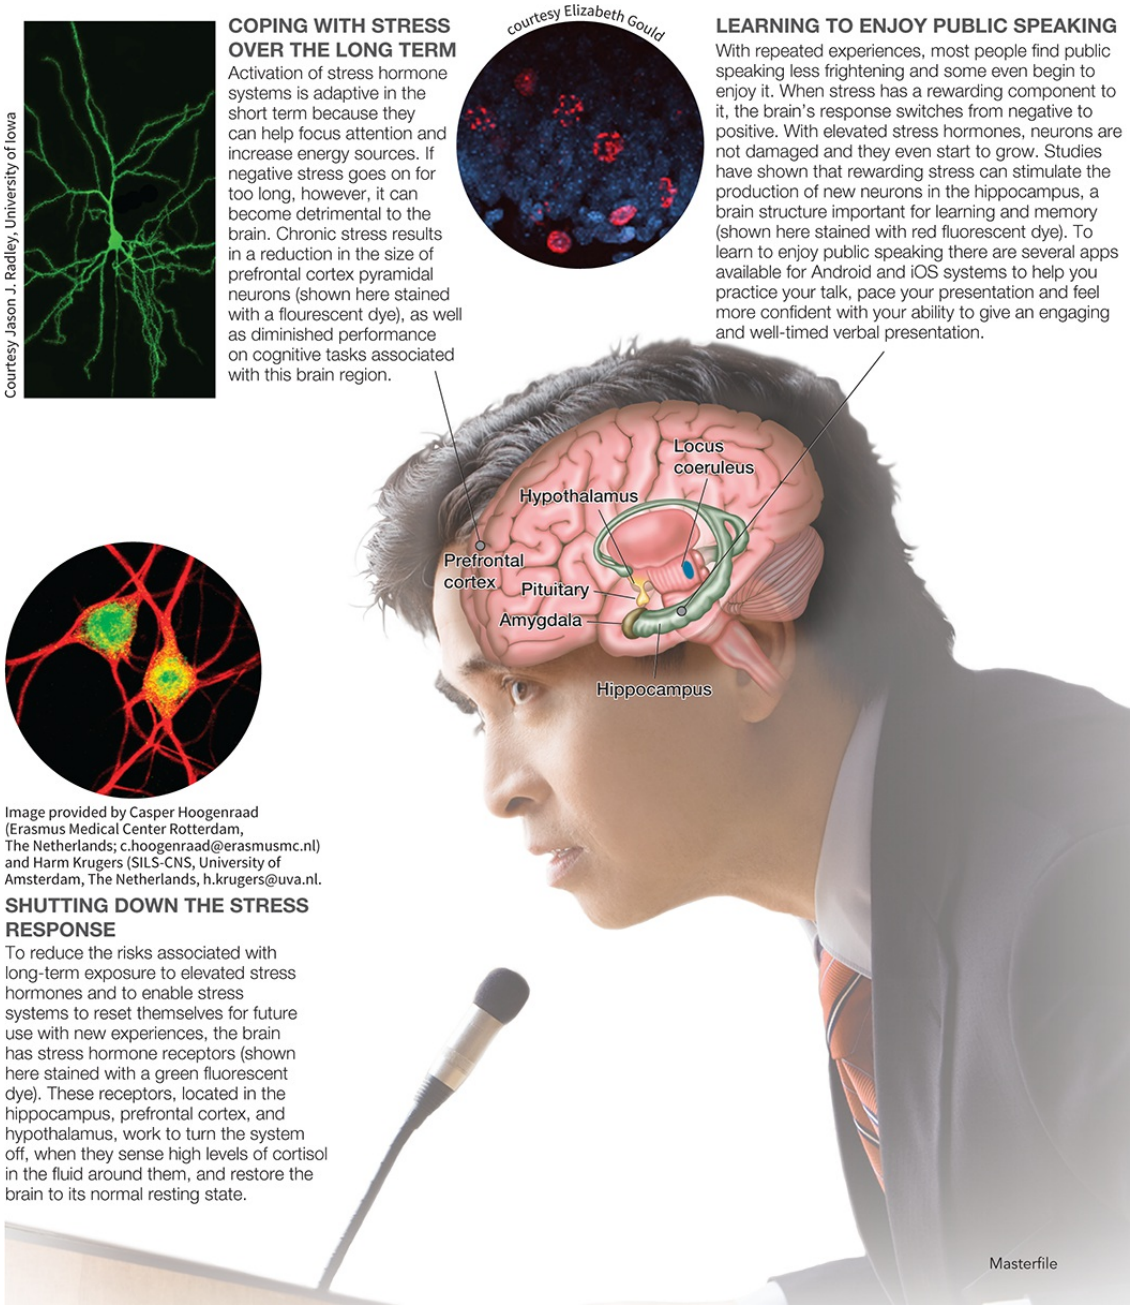
What is the role of the hypothalamus in responding to a stressor?

What does it mean to say that the effects of stress on the brain are helpful in the short term but can be harmful in the long term?

How does the brain response differ when a stressor is rewarding versus not rewarding?

Where in the brain are the stress hormone receptors that help to restore the brain to its normal state once the stressor has passed?

Fuse/Getty Images



Earlier, we discussed the Type A personality, which was identified by two cardiologists, Friedman and Rosenman. These doctors argued that the stress-producing behaviour of people with Type A personalities makes them more likely to develop coronary heart disease (see **Figure 14.5**). In fact, the Type A personality is also known in many circles as the *coronary-prone personality*. People with the more relaxed Type B behaviour pattern exhibit lower levels of stress and less coronary disease. In a pioneering study of more than 3,000 men, Friedman and Rosenman (1974) separated healthy men in their 40s and 50s into Type A and Type B groups and then followed their health over a period of eight years. The doctors found that more than twice as many of the Type A men developed coronary heart disease. Subsequent studies found similar correlations among women (Haynes,

Feinleib, & Kannel, 1980).

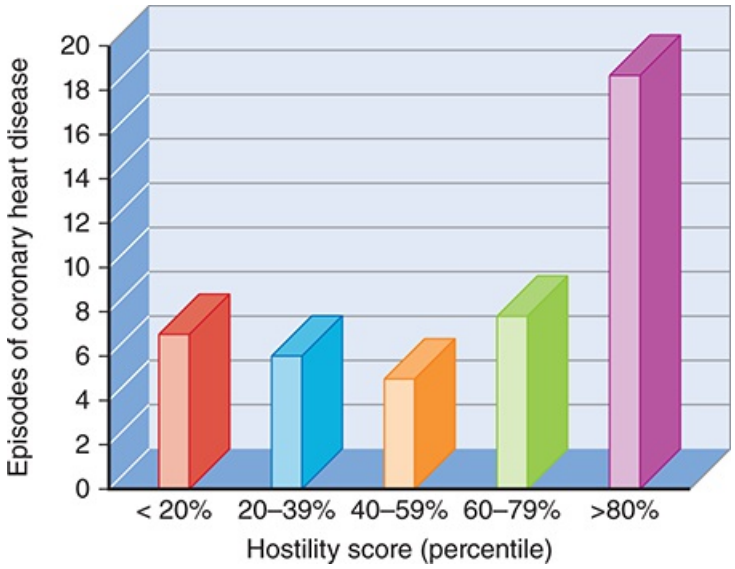


FIGURE 14.5 Type A personality and hostility A key characteristic of the Type A personality is chronic hostility. People with this personality style interact with others in a way that produces continual high levels of stress and increases their risk of coronary heart disease.

Source: Adapted from Niaura, R., et al. (2002). Hostility, the metabolic syndrome, and incident coronary heart disease. *Health Psychology*, 21, 588–593.

As research continued into the link between Type A behaviour and coronary heart disease, many investigators found that while a connection existed, it was weaker than that reported by Friedman and Rosenman (Gallacher et al., 2003). It now appears that only some of the Type A characteristics are strongly related to heart disease (Ben-Zur, 2002; Krantz & McCeney, 2002). In particular, research has identified the importance of negative emotions. Hostility, which includes not just feelings of anger but also enduring cognitive patterns of mistrust and cynicism, seems to be especially important (Smith & Gallo, 2001). (See photo.) People who score high on measures of hostility tend to experience greater stress and to have an increased risk of developing coronary heart disease, as well as other serious medical illnesses (Elovainio et al., 2011; Kendall-Tacket, 2010). More recent research has begun to suggest that aspects of Type D personalities (gloominess and social inhibition), discussed earlier in this chapter, may contribute to levels of coronary heart disease both directly (physiologically) and indirectly, through lower levels of social support (Ginting et al., 2016; Kupper & Denollet, 2018).

undergroundw/iStockphoto.com

Hostility and your heart **It is not surprising that individuals who score high on measures of hostility experience more stress and are at higher risk for heart attacks.**

Stress and the Immune System

Research clearly shows that stress can result in various medical disorders. But exactly how does this effect come about? What is it about stress that makes it a threat to health? An area of study called **psychoneuroimmunology** has tried to answer this question by examining the links between stress, the immune system, and health (Glaser & Kiecolt-Glaser, 2014; Kendall-Tackett, 2014, 2010).

> **psychoneuroimmunology** an area of study focusing on links between stress, the immune system, and health.

The **immune system** is the body's system of organs, tissues, and cells that identify and destroy foreign invaders, such as bacteria and viruses, and in some cases cancer cells. An important group of cells in the immune system are **lymphocytes**, white blood cells that circulate through the lymphatic system and the bloodstream. When stimulated by bacterial or viral invaders, lymphocytes act to help the body fight the invaders, often by destroying body cells that have been infected by the invaders.

> **immune system** the body's system of organs, tissues, and cells that identify and destroy foreign invaders, such as bacteria and viruses, as well as cancer cells.
>
> **lymphocytes** white blood cells that circulate through the body and destroy foreign invaders and cancer cells; important components of the immune system.

Researchers believe that severe stress can negatively affect the activity of lymphocytes, slowing them down and thus reducing a person's ability to fight off viral and bacterial infections (see **Figure 14.6**) (Dhabhar, 2011; Glaser & Kiecolt-Glaser, 2014). In a pioneering study, Roger Bartrop and his colleagues (1977) in New South Wales, Australia,

compared the immune systems of 26 people whose spouses had died 8 weeks earlier with those of 26 similar participants whose spouses had not died. Blood samples showed that lymphocyte functioning was significantly slower in the bereaved people than in the non-bereaved individuals (Bartrop et al., 1977). Recent work has confirmed this finding by comparing the health of spouses who care for partners with dementia. Health declines during the last stages of care but rebounds in the weeks after the death of the ill spouse. This effect, however, is tempered by the social system around the surviving spouse. The individuals who were socially isolated reported worse health than those with social support (Wilson et al., 2020). Similarly, other studies have shown poor immune system functioning in persons who are exposed to long-term social stressors, (Brodaty & Seeher, 2017; Glaser & Kiecolt-Glaser, 2014; Lovell, Moss, & Wetherell, 2011).

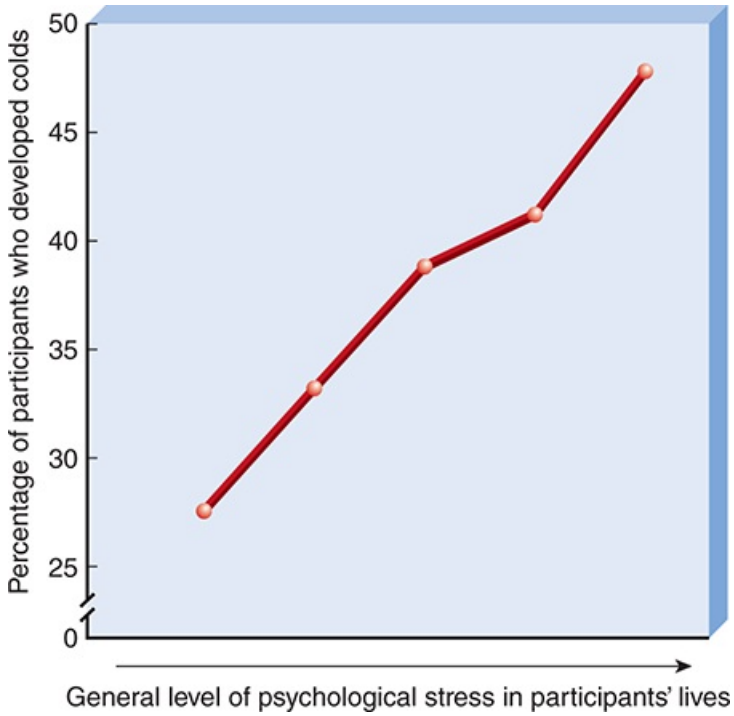

FIGURE 14.6 Stress and the common cold Researchers have examined the links between stress and illness. One study found that when healthy inoculation volunteers were exposed to a cold virus, those who generally reported the highest levels of stress in their lives were most likely to come down with a cold and to develop worse symptoms.

Source: Based on Cohen, S., Tyrrell, D. A. J., & Smith, A. P. (1991). Psychological stress and susceptibility to the common cold. *The New England Journal of Medicine*, 325, 609.

In short, during periods when healthy people confront unusual levels of stress, their immune systems slow down so that they become susceptible to illness. If stress adversely affects our very capacity to fight off illness, it is not surprising that Holmes and Rahe and other researchers have found a relationship between life stress and a wide range of illnesses. Several factors seem to influence whether and when stress will lead to immune system problems. A number of biochemical changes must occur for stress to have such an impact. Certain behavioural changes, personality styles, and social circumstances may also play a role (see Positive Psychology 14.2).

Biochemical Activity

Remember that when stressors first appear, the sympathetic nervous system springs into action. Its activity includes an increase in the release of norepinephrine throughout the brain and body. For example, beyond supporting the activity of the sympathetic nervous system, norepinephrine can eventually help slow the functioning of the immune system and increase the growth of infectious bacteria (Groer et al., 2010; Dhabhar, 2014; Sandrini, Algofaili, Freestone, & Yesilkaya, 2014). During periods of low stress, norepinephrine binds to particular lymphocyte receptors, and sends a message to lymphocytes to increase their activity (see photo). As stress rises and continues, however, the chemical travels to other receptors on the lymphocytes, binds to them, and gives an inhibitory message—a signal for the lymphocytes to stop their activity. Thus, the release of norepinephrine increases immune functioning at low levels of stress, but it slows down immune functioning in the face of higher and continuing stress.

14.2 Psychology Around Us | Positive Psychology

Laughter Yoga

As you've already read in the section on humour in this chapter, laughter does seem to be good for your health. Laughter as "medicine" can come in many forms and recent studies have shown that a type of yoga called laughter yoga can be beneficial in reducing circulating stress hormones (Meier et al., 2020). The practice of laughter yoga was popularized in 2002 by Madan Kataria in his book *Laugh for No Reason*. Laughter yoga uses prolonged voluntary laughter while participating in yoga breathing exercises as a strategy to reduce stress in participants. The laughter during this yoga is done for no apparent reason but practitioners have argued the brain doesn't seem to know we are faking it. While no brain imaging studies have been done comparing fake and authentic laughter, the sounds of authentic and forced laughter have been studied and are acoustically different (Lavan, Scott, & McGettigan, 2016; Ward, 2016).

Recent studies on laughter yoga report that it reduces the stress that cancer patients feel before undergoing chemotherapy and reduces stress in patients during blood dialysis. While its benefits for overall mental health are not yet clear, it does seem to hold promise for short-term reductions in anxiety and reduced depressive symptoms. It has also been reported to improve the general health of nursing students (Bennett et al., 2015; Bressington et al., 2018; Farifteh, Mohammadi-Aria, Kiamanesh, & Mofid, 2014; Yazdani, Esmaeilzadeh, Pahlavanzadeh, & Khaledi, 2014). Whether you are in poor health or not, laughter combined with yoga, at least in the short term, may be one way to get a daily or weekly bout of laughter in your busy life (Weinberg, Hammond, & Cummins, 2014).

Society Alzheimer Society

Laughter Yoga **Events such as this one where participants enjoy the combination of vigorous laughter with yoga have been held around the world over the last decade.**

Internal combat **This scanning electron micrograph shows a cancer cell being attacked by natural killer T-cells, a type of lymphocyte.**

Similarly, the stress hormone cortisol lowers immune system functioning during periods of extended stress. Recall that when people are under stress, their adrenal glands release cortisol. Initially, the release of this hormone stimulates body organs into action. After stress continues for 30 minutes or more, however, the stress hormone binds to receptor sites for cortisol that are found throughout the body, and turns off the body's stress response (Gjerstad, Lightman, & Spiga, 2018). Some of these receptor sites are located on the lymphocytes. When the cortisol binds to such receptors, its inhibitory messages slow down the activity of the immune system (Groer et al., 2010; Hechter, Halkerston, & Eichorn, 2012). Again, a chemical that initially helps people to deal with stress eventually acts to slow the immune system.

Another action of cortisol is to stimulate an increase in the production of *cytokines*—proteins that bind to receptors throughout the body and play a key role in activating the immune system. During acute stress, cytokines promote the activity of the immune system and stimulate the body's ability to fight infection. But as stress continues, the ongoing production of cytokines leads to chronic inflammation throughout the body (Burg et al.,

2011; Burg & Pickering, 2011; Carlberg, Ulven, & Molnár, 2016; Kendall-Tackett, 2014). *Inflammation* is an immune response characterized by swelling, heat, redness, and pain. Chronic inflammation of this kind may contribute to the development of cancer, heart disease, stroke, and metabolic disorders such as obesity and diabetes (Coussens, Zitvogel, & Palucka, 2013; Monteiro & Azevedo, 2010). Interestingly, one of the best behavioural changes a person can make to decrease chronic inflammation, similar to decreasing stress, is to exercise (Pedersen & Saltin, 2015).

Finally, investigators have learned that patterns of immune system response vary from individual to individual (Finkel, et al., 2014). Certain individuals experience more profound immune system slowdowns in the face of stress than other individuals do. Moreover, these individual differences in immune system functioning tend to be consistent across stressful situations. Thus, some stressed persons are more likely than others to develop infections and other diseases. Let's look next at some individual factors that may be responsible for differences in immune system functioning.

Behaviour, Personality, and Social Support

Stress may trigger a series of behavioural changes that affect the immune system indirectly (Elwenspoek, Kuehn, Muller, & Turner, 2017; Murphy, Cohen, Janicki-Deverts, & Doyle, 2017). People under chronic stress may, for example, become anxious or depressed, perhaps even develop an anxiety or mood disorder. In turn, they may eat poorly, exercise less, have trouble sleeping, or smoke or drink. Such behaviours are all known to slow down the immune system (Brooks, McCabe, & Schneiderman, 2011; Glaser & Kiecolt-Glaser, 2014; Kibler, Joshi, & Hughes, 2010). In workplaces, often Occupational Health and Safety guidelines are in place to help identify and provide assistance to employees who are experiencing these sorts of stress-related problems. You can see how industrial/organizational psychologists have contributed to this important area in the Psychology@Work video on Occupational Health and Safety.

Video **PSYCHOLOGY@WORK**

Occupational Health and Safety **The video looks at how industrial/organizational psychology and research into stress and other workplace issues is addressed by occupational health and safety practitioners.**

An individual's personality may also help determine how much the immune system is affected by stress. Studies suggest that people who typically respond to life stress with optimism, effective coping, and resilience tend to experience better immune system functioning and to be better prepared to combat illness (Kendall-Tackett, 2014; Kern & Friedman, 2011; Williams et al., 2011). Correspondingly, those with "hardy" or resilient personalities tend to remain healthy after stressful events, whereas those whose personal styles are less hardy are more vulnerable to illness (Bonanno et al., 2010; Maddi, 2016).

Several studies have actually noted a relationship between certain personality characteristics and cancer (Hjerl et al., 2003). People exhibiting the Type C behaviour pattern appear to be more at risk for cancer. Recall that people with the Type C personality have trouble acknowledging negative feelings and may be particularly vulnerable to stress.

In addition, some studies have found that patients with certain forms of cancer who display a helpless or repressive coping style tend to have less successful recoveries than patients who express their emotions. It is important to note, however, that other studies have found no relationship between personality and cancer outcome (Jokela, et al., 2014). Type D personality may also be implicated both in higher cancer rates and in poorer quality of life following cancer treatment (Fleming, Wiencierz, & Williams, 2016).

A few studies have also linked spirituality to better immune system functioning. A recent meta-analysis has shown that the social support individuals with similar spiritual beliefs and practices can lead to a reduction in the circulating immune system proteins that promote inflammation. This can can lead to reduced blood pressure and better cardiovascular health. (Jackson & Bergeman, 2011; Shattuck & Muehlenbein, 2018).

Chris Arend/Getty Images

Healthy communities **This group of Inuit perform a "blanket toss" ceremony in which they form a ring around a blanket and use it to hurl group members into the air. Communities that share activities and remain close-knit often have lower illness rates than other communities.**

More generally, research indicates that social support helps to protect us from the effects of stress. People who have little social support and feel lonely, such as those with Type D personalties (Ginting et al., 2016), tend to experience poorer immune functioning when

stressed than other people do (Uchino & Birmingham, 2011; van Dooren et al., 2016). Conversely, it appears that social support helps protect people from stress, poor immune system functioning, and illness and helps improve recovery from illness or surgery (Glaser & Kiecolt-Glaser, 2014; Murphy, Cohen, Janicki-Deverts, & Doyle, 2017). Some studies have even suggested that patients with certain kinds of cancer who receive social support or supportive therapy often display better immune system functioning and, in turn, have more successful recoveries than patients without such social help.

The stress-reducing benefits of social support can be seen in the health of people who grow up in close-knit communities (see photo). One early study explored the low rate of stress-related illnesses among residents of the town of Roseto, Pennsylvania (Wolf, 1969). The death rate from coronary heart disease in this town was considerably lower than that in the general population, despite the fact that the residents' eating, smoking, and exercise patterns were similar to those in communities with much higher coronary death rates. Clearly, something special was responsible for the residents' good health. That something turned out to be Roseto's positive social environment. An Italian enclave, Roseto was home to extremely close, supportive, and traditional families. Relatives, friends, and local priests were always available to help out with any kind of problem. During the 1970s, Roseto's younger generation began to marry people from other backgrounds and move away. Church attendance also dropped. These social changes resulted in less social support throughout the community. Perhaps not surprisingly, the rate of heart attacks in the community increased (Greenberg, 1978).

The Benefits of Stress

It might be hard to believe, given the litany of problems that we have identified here, but stress can be positive. In fact, when Selye first identified stress as a concept back in 1936, he actually drew a distinction between unpleasant stressors and pleasant stressors. How can a stressor be pleasant? Think about waiting for a text from someone you met at a party last night; it can be stressful, but in an exciting way. Unpleasant stressors, according to Selye, cause **distress**—the kind of unpleasant stress on which we have generally been focusing up to now. Pleasant stressors, in contrast, cause *eustress.*

> **distress** stress caused by unpleasant situations or circumstances.

A key benefit of stress is that it helps promote positive development. Remember in Chapter 4 when we discussed some theorists' notion that parents can actually stunt a baby's development by meeting all the baby's needs, and that there is some optimal level of frustration that facilitates development? Researchers have suggested that similar principles apply across the lifespan. That is, adverse events and the stress that they produce can force you to confront challenges, adapt to your environment, and build up strength and resilience in a manner referred to as *posttraumatic growth* (Dooley et al., 2017; Tedeschi, Shakespeare-Finch, Taku, & Calhoun, 2018; Vázquez, Pérez-Sales, & Ochoa, 2014).

Today, **eustress** is defined not in terms of the stressor, but in terms of the stress level—it is the optimal level of stress that promotes physical and psychological health (Hargrove, Nelson, & Cooper, 2013; Hargrove, Becker, & Hargrove, 2015). But what exactly is an

optimal level of stress? We can think about this question in a couple of ways. First, exposing yourself to a smaller level of stress in a controlled situation can improve your performance in a more stressful situation, a process called **inoculation** (see photo). If you call one friend to talk through what you want to say to another friend with whom you have been arguing, you are inoculating yourself.

eustress the optimal level of stress needed to promote physical and psychological health.

inoculation exposing oneself to a relatively low level of stress in a controlled situation to improve later performance in a more stressful situation.

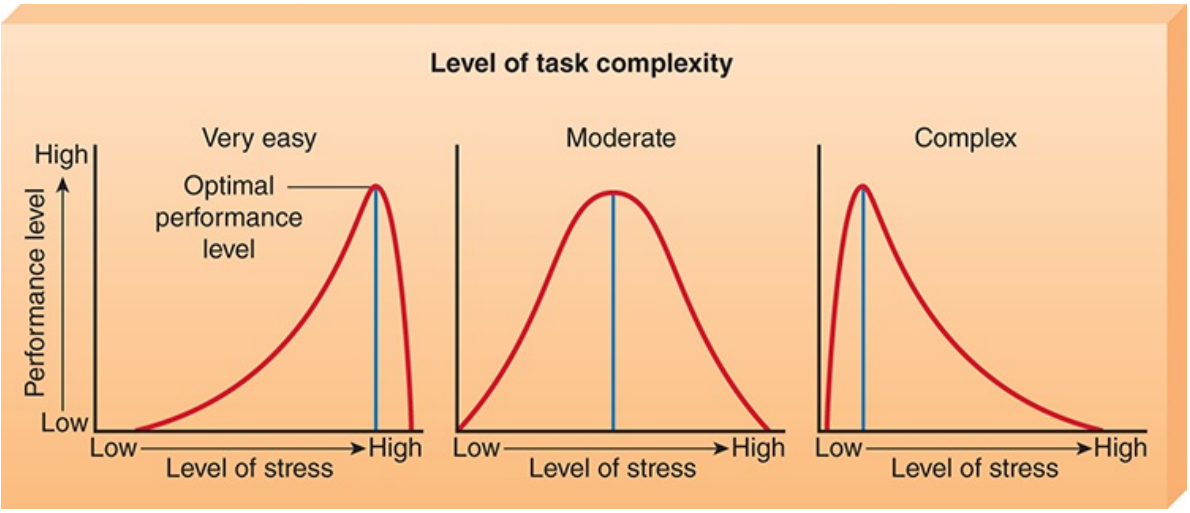

FIGURE 14.7 Stress and performance **Stress can actually benefit performance, depending on the complexity of the task. On very complex tasks, a low level of stress is optimal for performing your best; on very easy tasks, a high stress level helps you stay focused. Based on Weiten, W. (2004). *Psychology: Themes and variations* (6th ed.). Belmont, CA: Wadsworth, Figure 13.5, p. 528.**

Shannon Stapleton/Reuters - Images

Stress inoculation? Why is this drill instructor screaming at this poor recruit? The logic behind this time-honoured training technique is that intense stressors experienced during basic training will build mental strength and resilience and make individuals more effective in actual combat.

As we have seen previously, another way of considering what constitutes an optimal level of stress involves looking at the relationship between stress and performance. As shown in Figure 14.7, researchers have found that stress can actually facilitate performance on a task, depending on the complexity of the task.

Performance of very easy tasks can benefit from a high level of stress. For example, the old videogame Tetris®, which is experiencing a resurgence, involves very little cognitive complexity and very low stakes, but as the computer starts dropping the pieces faster, it will get your attention and help you stay focused on the game.

A moderately difficult task benefits from a moderate level of stress. Too low, and you won't get excited enough to perform your best. Too high, and you will be more likely to lose your focus or perform poorly.

For a complex task, low stress leads to the optimal performance. Consider that the next time you decide to make a complex dinner you have never prepared before for a few friends and don't leave quite enough time to get your house cleaned and everything prepared before they arrive. You might do better ordering out.

18. What factors influence whether stress will have this effect?

19. What are some beneficial effects of stress?

What Do You Think? • Try to recall five events in your life or in the lives of your family members and friends that suggest a relationship between stress and illness. How might you account for those events and relationships?

Posttraumatic Stress Disorder

LEARNING OBJECTIVE 5

Describe the symptoms and causes of posttraumatic stress disorder, and discuss some risk factors for developing it.

As we have seen, stress, when moderate and handled constructively, can serve us well. But it can also work against us. In addition to leading to physical diseases, it can contribute to various psychological disorders, from depression to sexual dysfunctions. Moreover, it plays a central role in *posttraumatic stress disorder*, or *PTSD*, mentioned earlier in the chapter.

Wolfgang Rattay/Reuters - Images

PTSD Survivors mourn the dozens of teenagers and young adults killed by a lone gunman on July 22, 2011, at Utoeya, a youth camp for Norway's Labour Party.

In posttraumatic stress disorder, persons who have confronted an extraordinarily stressful event—combat, sexual assault, earthquake, airplane crash, automobile accident, terrorist

attack, or pandemic—experience a number of severe psychological symptoms lasting for months or even years (Shiromani, Keane, & LeDoux, 2014). They have lingering reactions of intense fear and helplessness. They may be battered by memories, dreams, or nightmares connected to the traumatic event, and may repeatedly try to avoid activities, thoughts, feelings, or conversations that remind them of the event. Many also feel detached from other people, some lose interest in activities that once brought enjoyment, and some feel dazed. A number of individuals with the disorder are easily startled, develop sleep problems, and have trouble concentrating. They may also feel extreme guilt because they survived the traumatic event while others did not (Shiromani et al., 2014). (See photo.)

While any traumatic event can trigger PTSD, certain events are particularly likely to do so. The most common causes of PTSD are combat, natural disasters, abuse, and victimization (Shiromani et al., 2014). As well, people who are victims of terrorism, or who live with the fear of terrorism, often experience posttraumatic stress symptoms (Hansen et al., 2017; Slone & Mann, 2016). Many people will forever remember the events of September 11, 2001, when hijacked airplanes crashed into the World Trade Center in New York City and damaged the Pentagon in Washington, D.C. One effect of these terrorist attacks is the lingering psychological effect on the people who were directly affected and their family members, as well as on millions of others who watched images of the disasters on their television sets throughout that day. The stressful effects of this attack, in many cases PTSD, are still felt by individuals who experienced this traumatic event (Lowell et al., 2018; Welch et al., 2016).

Who Develops PTSD?

Recent work suggests that as many as 2.5 million Canadians and 70,000 first responders (firefighters, police, emergency medical service workers) suffer from PTSD at some point in their lives (Wilson, Guliani, & Boichev, 2016). The disorder can occur at any age, even in childhood (Gutermann et al., 2016). Women appear to be more likely than men to develop PTSD (Christiansen & Hansen, 2015; Pineles, Hall, & Rasmusson, 2017).

Although anyone who experiences an unusual trauma will be affected by it, only some people develop posttraumatic stress disorder (Sayed, Iacoviello, & Charney, 2015). (See photo.) To understand the development of this disorder more fully, researchers have looked at the same stress-related factors that we have examined throughout this chapter—and they have come up with promising leads.

Biological Factors

As we have observed, stressors trigger biochemical reactions throughout the brain and body. Apparently, in the face of extraordinarily threatening stressors, some people develop particularly strong biochemical reactions—reactions that continue well beyond a short-term fight-or-flight period. It appears that such individuals are more likely than others to experience a posttraumatic stress disorder (Zoladz & Diamond, 2013; Bremner & Charney, 2010; Pace & Heim, 2011). Consistent with this notion, researchers have found abnormal activity of the stress hormone cortisol and the neurotransmitter norepinephrine in the urine and blood of combat soldiers, sexual assault victims, concentration camp survivors, and survivors of other traumatic events (Burijon, 2007; Delahanty et al., 2005; Pan et al., 2018).

STRDEL/Stringer/Getty Images

Is anyone immune? Rescuers pull a survivor from the rubble of a collapsed garment factory in Bangladesh in May 2013. Most people who experience extraordinary traumatic events are capable of developing PTSD. Even rescue workers at the site of disasters often develop the disorder. Nevertheless, all things being equal, some people seem more prone to PTSD in the aftermath of traumatic events.

Indeed, some studies suggest that people who develop PTSD have exaggerated sympathetic nervous system responses and blunted HPA axis responses to stress; however, the data is currently non-conclusive (Dunlop & Wong, 2019). There is also some evidence that once a posttraumatic stress disorder sets in, the individual's continuing biochemical arousal may eventually shrink the hippocampus, one of the brain areas that helps control the body's stress hormones, thus further locking in the disorder (Kim, Pellman, & Kim, 2015). At the same time, it is worth noting that, according to some research, people who are more susceptible to developing PTSD may have a smaller hippocampus to begin with (Greenberg et al., 2014).

Personality

Earlier, we observed that people with certain personality styles or coping styles are particularly likely to react to threats with stress and to develop medical problems. Similarly, such styles increase the likelihood of developing a posttraumatic stress disorder (Campbell, Renshaw, & Righter, 2015). It turns out, for example, that people with less resilient, or less hardy, personality styles appear more likely to develop a posttraumatic stress disorder than those with more resilient styles (Horn, Charney, & Feder, 2016; Kunst, 2011). Interestingly, the personality trait that seems to be associated with less severe PTSD-like symptoms, or greater resilience after a traumatic event, is psychological flexibility. A person's ability to adapt to changing demands in their environment, shift their perspective, and reassess and reconfigure their mental resources seem to be key personality traits for managing PTSD (Kashdan & Rottenberg, 2010; Meyer, Kotte, et al., 2019; Meyer, La Bash, et al., 2019).

Childhood Experience

Studies have also suggested that certain childhood experiences increase the risk of later posttraumatic stress disorders (Alter & Hen, 2009; Brockie et al., 2015; Rapee & Bryant, 2009). (See photo.) People whose childhoods have been characterized by poverty appear more likely to develop this disorder when later confronting horrific events. So are people whose parents displayed psychological disorders and who experienced assault, abuse, or catastrophe at a young age (Gutermann et al., 2016).

Detecting PTSD in children **The Sesame Street Muppet Rosita tells children in New York about "You Can Ask," a program that seeks to identify and deal with stress in children. The program was first formed in the aftermath of the September 11, 2001 terrorist attacks.**

Social Support

Finally, the social environment may influence whether victims of traumatic events develop

posttraumatic stress disorders. Earlier, we saw that inadequate social support can intensify stress reactions and slow down immune system functioning. Thus, it is not surprising that people with strong social support systems are more likely to recover, or cope better with, a posttraumatic stress disorder after a traumatic event (than those with weak social support systems (Olff et al., 2014). (Maheux & Price, 2016; Stanley et al., 2018) For example, sexual assault victims who feel loved, cared for, and accepted by their friends and relatives tend to recover more successfully (Dworkin et al., 2018; Ullman & Peter-Hagene, 2016).

We will look at posttraumatic stress disorder in greater detail in Chapter 15. In the meantime, the current discussion helps clarify once again that stress is a very powerful force. Moreover, when it is overwhelming or dealt with ineffectively, it can totally disrupt our functioning and our lives.

Before You Go On

(Answers to Before You Go On may be found online in the Course Resources.)

What Do You Know?

20. What are some symptoms of posttraumatic stress disorder?

21. What factors put a person at heightened risk for developing posttraumatic stress disorder following a traumatic event?

What Do You Think? • Try to recall five events in your life or in the lives of your family members and friends that suggest a relationship between stress and illness. Having now read this chapter, how might you account for those events and relationships?

Summary

What Is Stress?

LEARNING OBJECTIVE 1 Define stress and describe the ways in which people experience stress and the kinds of situations that typically cause stress.

Stress is a state brought on by any situation that threatens or appears to threaten a person's sense of well-being, thus challenging the person's ability to cope. A situation that triggers the stress response is a stressor. A stressor may be acute (short term) or chronic (long term).

People may experience stress as frustration, pressure, conflict, or danger.

Kinds of stressors include daily hassles, life changes (which can be measured by the Social Readjustment Rating Scale), traumatic events, chronic negative situations, and special socio-cultural conditions.

Responding to Stress

LEARNING OBJECTIVE 2 Describe the physiological, emotional, and cognitive responses to stress, and explain how individual responses to stress differ.

There are two main physiological pathways of stress: the sympathetic nervous system and the hypothalamic-pituitary-adrenal axis. Both lead to activation of the fight-or-flight response, which is an immediate response to a stressor.

Hans Selye first described the effects of chronic stress, which he called the general adaptation syndrome (GAS). The syndrome has three stages: alarm, resistance, and exhaustion.

Emotional responses to stress generally involve negative emotions. The more stress a person experiences, the more negative the emotions.

Cognitive appraisal is an important element in responses to stress. Richard Lazarus identified two steps in this process: *primary appraisal*, in which people assess the severity of the stressor, and *secondary appraisal*, in which they evaluate how well they can cope with it.

Individuals vary greatly in their responses to stress. Areas of difference include autonomic activity, explanatory style, personality, and availability of social support.

Coping with Stress

LEARNING OBJECTIVE 3 Discuss and evaluate several ways in which people cope with stress.

Coping describes efforts to manage, reduce, or tolerate stress.

Dealing with stress by lashing out at others, using defence mechanisms such as repression, and engaging in self-indulgent behaviours such as smoking or drinking alcohol can be destructive when used in excess.

More constructive coping strategies include directly confronting a stressor in hopes of changing the situation (*problem-focused coping*) and changing how you feel or think about the stressor to reduce its impact (*emotion-focused coping*).

Stress and Health

LEARNING OBJECTIVE 4 Explain how stress can cause physical illness, and discuss situations in which stress may be beneficial.

Stress can increase risk for a number of health problems. People with *Type A* personalities are prone to stress and appear to be at greater risk for coronary heart disease than the more relaxed *Type B* personalities. Using the Social Readjustment Rating Scale, researchers have found that stress-producing life changes also increase the risk of illness. *Type C* personalities are more vulnerable as they tend to internalize their anger and cope badly with relationship challenges. *Type D* personalities are more vulnerable because they tend to cut themselves off from social supports.

Psychoimmunology is an area of study that examines the links between stress, the immune system, and health.

Severe stress may interfere with the activity of *lymphocytes*, a component of the

immune system that helps the body to overcome invaders, such as bacteria and viruses.

Stress-related biochemical changes in the body, such as changes in the activity of norepinephrine and cortisol, can eventually slow the functioning of the immune system.

Behaviour, personality, and social support are additional factors affecting how much the immune system is slowed down by stress.

Unlike *distress*, or negative stress, *eustress* offers benefits. Optimal levels of stress can promote the development of resilience and facilitate performance, especially for easy or moderately difficult tasks.

Posttraumatic Stress Disorder

LEARNING OBJECTIVE 5 Describe the symptoms and causes of posttraumatic stress disorder, and discuss some risk factors for developing it.

Posttraumatic stress disorder is characterized by persistent, frightening thoughts or memories of a traumatic event, along with anxiety, depression, and other symptoms.

Combat, natural disasters, and abuse and victimization are among the events most likely to cause posttraumatic stress disorder.

Not everyone affected by unusual trauma develops posttraumatic stress disorder. Factors that affect the likelihood of developing the disorder include biological factors, personality factors, childhood experiences, and the availability of social support.

Self-Study Questions

Multiple Choice

1. The sweaty palms and rapid heartbeat we experience as anxiety are most directly related to activation of which portion of the nervous system?

- **a.** Autonomic nervous system
- **b.** Hippocampus
- **c.** Occipital lobes
- **d.** Sympathetic nervous system

2. Compared with major life events, daily hassles

- **a.** have a lower impact upon us.
- **b.** can add to the effects of larger events.
- **c.** can have greater impact than the effects of major life events.
- **d.** are of secondary concern.

3. Bob loves visiting his grandfather but hates his cooking. Bob is trying to decide whether to visit his grandfather this weekend and is experiencing an

a. approach–approach conflict.

b. approach–avoidance conflict.

c. avoidance–avoidance conflict.

d. approach–withdraw conflict.

4. During concentrative meditation, a person actively concentrates on an object, word, or idea called a(n) _____.

a. dissociation

b. koan

c. mantra

d. suggestion

5. Which of the following is not potentially associated with posttraumatic stress disorder?

a. Anxiety

b. Depression

c. Amnesia

d. Disorientation

6. What does the release of cortisol during stressful experiences do for us?

a. Elevates blood sugar

b. Energizes us

c. Protects us from inflammation

d. All of the above

7. Which of the following is one experience that can lead to feeling stressed?

a. Automatic

b. Frustration

c. Happiness

d. Sensitization

8. In a study using the Social Readjustment Rating Scale, which of the following stressors was not reported as one of the top five experienced by college and university students?

a. Applying to graduate school

b. Death of a family member or friend

c. Having to take multiple tests

d. Personal injury or illness

9. Which of the following statements shows the correct order of the components of the physiological response to stress?

a. hypothalamus → adrenal cortex → pituitary

b. hypothalamus → adrenal medulla → pituitary

c. hypothalamus → pituitary → adrenal cortex

d. hypothalamus → pituitary → adrenal medulla

10. Recent research has shown that _____ is the aspect of Type A personality that is most strongly associated with coronary heart disease.

a. competitiveness

b. hostility

c. impatience

d. pessimism

11. Which type of task is best suited to moderate levels of stress?

a. Easy

b. Medium

c. Difficult

d. None of these; moderate stress is the optimal stress level for all types of tasks.

Fill-in-the-Blank

1. When we are deciding what a particular situation means to us in terms of its stress potential, we are _____ the situation.

2. If your friends were to forget to invite you to a party, it would be an example of a _____ stressor.

3. If you were to complete the Social Readjustment Rating Scale in a research project, you would be assigned a _____.

4. When a minority-group member encounters members of the majority group, they may experience _____ threat.

5. In the resistance phase of the general adaptation syndrome, our resistance level to the effects of stress is _____ relative to unstressed levels.

6. The fact that a given situation may be very stressful for one person and not at all stressful for another tells us that the _____ of threat is often more important than actual threat.

7. Emily is struggling to keep up with her classes and must choose whether to work on a paper for one class or a project for another class before heading to work. Emily is facing a(n) _____ conflict.

8. _____ meditation has been shown to relieve pain by encouraging people to pay

attention to their feelings, sensations, and experiences without judging or getting too involved with them.

9. When faced with a stressor, the nervous system communicates with the endocrine system via the _____ axis.

10. Although early research showed that having a Type A personality was related to the risk of coronary heart disease, recent studies have shown that the cluster of negative emotions called _____ is a better predictor of risk.

11. _____ is a neurotransmitter that tends to improve immune system functioning in times of low stress and impair it during periods of severe or prolonged stress.

CHAPTER 15
Psychological Disorders

Stanislaw Mikulski/Shutterstock

CHAPTER OUTLINE

Defining, Classifying, and Diagnosing Psychological Abnormality

LEARNING OBJECTIVE 1 Identify the common features of most definitions of abnormal functioning, and describe how psychological disorders are classified and diagnosed.

Models of Abnormality

LEARNING OBJECTIVE 2 Describe the major models used by psychologists to explain abnormal functioning.

Mood Disorders

LEARNING OBJECTIVE 3 Describe and differentiate major depressive disorder and bipolar disorder.

Anxiety Disorders

LEARNING OBJECTIVE 4 Describe the various types of anxiety disorders, and explain some causes of these disorders.

Schizophrenia

LEARNING OBJECTIVE 5 Describe the features of schizophrenia and some theories of what causes it.

Other Disorders

LEARNING OBJECTIVE 6 Discuss the features and possible causes of somatic symptom and related disorders, dissociative, and personality disorders.

Diane Markos, a 27-year-old single female, struggled with depression. Within a period of three months, she lost 7 kilograms and she felt tired all the time. She withdrew from nearly all her usual social activities and she openly acknowledged thoughts of overdosing on pills. Previous psychotherapy and treatment with antidepressant medication had produced no improvement. She was referred to a psychologist for additional treatment.

Diane's changes over the three months occurred shortly after the breakup of a relationship she had been having with a man for approximately two years. She now saw herself as fat, unattractive, and doomed to be alone. Although she had never had a wide circle of friends, the past two years had seen her social contacts become even more limited. Other than the few evenings that she spent with her boyfriend, she had gradually managed to work herself into a life of all work and no play, and she was intensely lonely.

Diane lived alone and worked full-time as a pediatric nurse while pursuing a master's degree part-time in nursing. Although she was a straight-A student, she had numerous interpersonal difficulties with fellow students and instructors. Her relations with co-workers were similarly troubled. Although she had a reputation as a good staff nurse, she had never been able to obtain a supervisory position because of her ongoing interpersonal conflicts.

Diane's early family history provided some clues to the sources of her current difficulties. As the eldest of three children, she was frequently expected to play the role of caretaker for her younger siblings. She felt that her parents' love was contingent on her playing the role of "mother's little helper." She believed that her sister and brother had been allowed to lead a much more carefree childhood.

In short, Diane saw her past and present as an unhappy life of servitude, rejection, and failure. And she could envision no other scenario for her future. She felt quite hopeless, and as a result her new therapist considered her to be a serious suicide risk (Taylor et al., 2011).

Throughout this book we have examined the nature of behaviour and mental functioning, from sensations to memory to personality. Most of our discussions have looked at "typical" functioning. And indeed, our mental life and behaviour are fascinating and complex even when they do not go astray. However, as we have repeatedly observed, functioning often does go astray. We are immediately reminded of this as we read about Diane Markos. Most who hear about Diane would likely agree that her depressed mood, isolated behaviour, and negative thinking are far from functional.

You have already come across a few of the leading psychological disorders while reading the Atypical Development sections throughout this book. In this chapter, we will be looking even more closely at the topic of abnormal psychological functioning (see paintings). First, we will see that although most people believe they know abnormal functioning when they see it, it is, in fact, a difficult concept to define. Then, we will explore the ways in which psychologists classify, assess, and explain the various kinds of abnormal functioning. In the next chapter, we will examine how mental health practitioners try to help the individuals whose behaviours, thoughts, or emotions are dysfunctional—individuals known as *clients* or *patients* when seen in mental health settings.

Print Collector/Getty Images

Bettmann/Getty Images

Art and psychological disorders **Many of our greatest paintings focus on psychological dysfunction. Two of the most famous are *The Scream*, by Edvard Munch, which brings symptoms of anxiety and panic to life, and *Portrait of Dr. Gachet*, by Vincent van Gogh, about depression.**

Defining, Classifying, and Diagnosing Psychological Abnormality

LEARNING OBJECTIVE 1

Identify the common features of most definitions of abnormal functioning, and describe how psychological disorders are classified and diagnosed.

Diane Markos's emotions, behaviours, and thoughts appear to be atypical, the result of states sometimes referred to as *psychological dysfunctioning*, *psychopathology*, *psychological disorders*, or *mental disorders*. The field devoted to the scientific study of psychological disorders is usually called **abnormal psychology**.

abnormal psychology the scientific study of psychological disorders.

Abnormal psychological functioning is a wide-ranging problem, as indicated in **Figure 15.1**. It has been estimated that in a given year, at least 20 percent of adults in Canada experience serious psychological disturbances (Canadian Mental Health Association, 2014b) and the rate for 20- to 29-year-olds is closer to 28 percent (Mental Health

Commission of Canada, 2013). The numbers and rates in other countries are similar (Andreas et al., 2017; Steel et al., 2014; Polanczyk et al., 2015).

Furthermore, many people go through periods of great tension, upset, or other forms of psychological discomfort in their lives. At such times, they experience at least some of the distress found in psychological disorders.

What are your thoughts regarding the causes of mental illness? Throughout history, humans have speculated about the causes of the abnormal behaviours that seem to be a part of the human condition. In ancient times, there is evidence that "madness" was seen as a sign of demonic possession or of witch or warlock status. In many cases the "cures" were not particularly helpful to the individuals involved, given that they were intended to cast out evil spirits by burning or drowning. Many people did not survive their "cures." In more recent times, things were not much better for the mentally ill. A lack of understanding of the causes of mental illness led to a general belief that afflicted individuals were of inferior character, even less than human (Schwab, 2013). In the 1700s in the United Kingdom, those families that could afford it often hid their mentally ill relatives away and cared for them in isolation. Those who could not afford this had few options. Many "mad" people were left at places like Bethlehem Hospital in London, where care was minimal and the use of restraints typical. Tours through the hospital to see the mad people were a major source of revenue for the hospital (Northwood, 2014; Andrews et al., 1997).

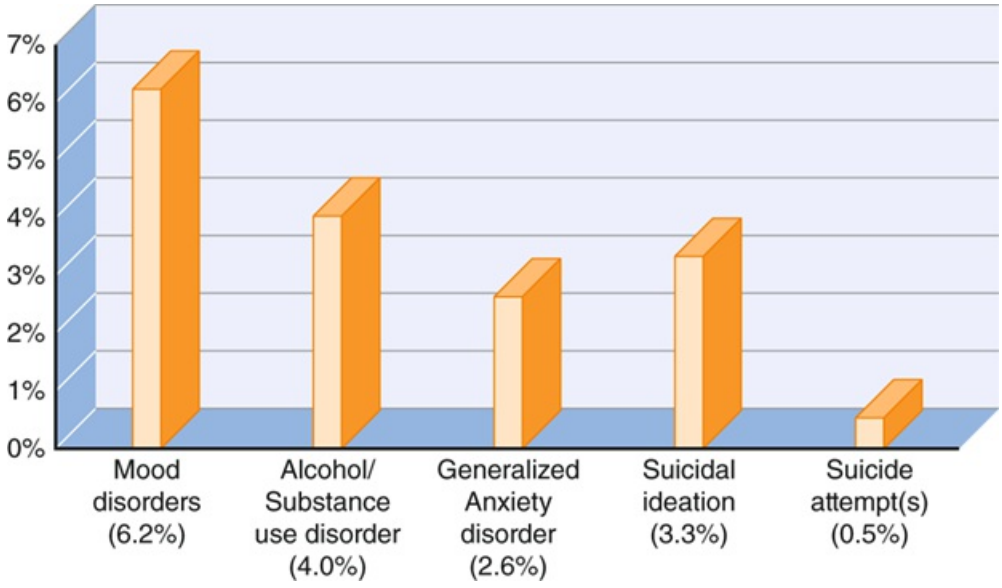

FIGURE 15.1 How many people are diagnosed with mental disorders each year? Nearly one-quarter of the adults in Canada each year experience symptoms that qualify for a diagnosis of at least one mental disorder.

Source: Palay et al. (2019). Prevalence of mental disorders and suicidality in Canadian provinces. *The Canadian Journal of Psychiatry*, *64*(11), 761–769.

While many argued for more humanitarian treatment for the mentally ill, reform movements did not really gain any ground until a clear connection was made between physical illness and madness. A condition called general paresis was well-known in medical circles (Beck & Tompkins, 2016). It usually afflicted males between 20 and 40 years of age.

Initial symptoms included memory loss (short and long term), impairment of judgment, and decreases in motivation and language. Later symptoms included delusions and hallucinations, inappropriate moods and/or anger, and eventually full-blown dementia, seizures, and death. The symptoms progressed over a few months to at most one or two years, and death was inevitable. When it was discovered that general paresis was the result of a sexually transmitted infection, syphilis, two things resulted (Brown, 2008). First, it was possible to treat syphilis and avoid general paresis; second, it clearly showed that the signs of madness could be symptoms of an underlying physical illness. This gave strong support to mental health reform movements such as *moral treatment*, which led to more humane treatment for the mentally ill (Manning, 2013; Eastoe, 2020).

Historical/Getty Images

Early interventions **Benjamin Rush, a doctor and signatory to the American constitution, developed the tranquilizing chair shown here. It was believed to calm mental patients by reducing blood flow to the head.**

The *medical model* approach to understanding and treating mental illness has been a major influence on our thinking and practices in assisting those struggling with mental illness over the past century (see illustration). The medical model encourages a search for patterns in the symptoms people present with the goal of first identifying a syndrome—a collection of symptoms, like general paresis—that is recognized and about which one can make predictions. In the case of general paresis, the predictions made about prognosis were accurate but deadly. The next step involves a search for possible causes of the observed symptoms. Hopefully the identification of underlying causes also suggests viable treatments (Huda, 2019).

As we will see later in this chapter and in the next chapter, when we look at treatment approaches, the biological basis of the medical model approach to mental illness certainly

has significant research support. We will also see, however, that there are serious concerns about the limitations of the medical model. By focusing on physical/biological causes, the medical model takes focus away from the possible roles played by psychological processes and socio-cultural circumstances on mental illness and mental health (Tyrer, 2013). In the rest of this chapter we will provide you with a sense of these broader perspectives in mental illness and mental health.

Defining Psychological Abnormality

How do we know that someone is functioning abnormally? In other words, what is psychological abnormality? This question is not easy to answer. Although many definitions of abnormality have been proposed over the years, none is universally accepted (Pilgrim, 2014). Nevertheless, most of the definitions have key features in common, often called "the four Ds": deviance, distress, dysfunction, and danger.

Deviance Behaviour, thoughts, and emotions are considered abnormal when they deviate from a society's ideas about proper functioning. Judgments of deviance and abnormality vary from society to society. A society that values competition and dominance may embrace aggressive behaviour, whereas one that emphasizes cooperation may consider such behaviour unacceptable and even abnormal (Eller, 2016). Moreover, a society's values may change over time, leading to a new societal view of what is psychologically abnormal. In Western society, for example, a woman's participation in athletics, academia, or business was considered unusual and even inappropriate 100 years ago (Matsumoto & Juang, 2016). Today, people in Western cultures value that behaviour.

Distress To be considered abnormal, behaviours, ideas, or emotions usually must also cause distress or unhappiness (Matthews, 2016). For example, Diane Markos from the opening case feels upset and burdened most of the time by her negative feelings and thoughts and the impact they are having on her life.

Dysfunction Abnormal behaviour also tends to interfere with daily functioning, as opposed to behaviour that is simply eccentric but a part of a person's life. When behaviour upsets people so that they cannot take proper care of themselves, interact well with others, or work effectively, then it is referred to as abnormal. For example, Diane's behaviours have contributed to social isolation, problems at work, and conflicts at school.

Danger Some people with psychological dysfunction are more likely to become dangerous to themselves but are less likely to harm others. If, for example, individuals are consistently hostile or confused, they may put themselves, family members, or friends at risk. Recall that Diane Markos's thoughts of overdosing on pills led her therapist to consider her a serious suicide risk. It is important to note that while the incidence of violence among the mentally ill is slightly higher than in the general population, it is often linked more directly to associated issues of substance abuse (Van Dorn et al., 2017). Despite popular views, most people who are greatly troubled or even out of touch with reality pose no immediate danger to themselves or anyone else (Reavley, Jorm, & Morgan, 2016).

AP Photo/RAJESH NIRGUDE

Does dysfunction equal abnormality? In this photo, a Tibetan man set himself on fire to protest China's occupation of Tibet. In this context, such behaviour, while self-harming, does not, by itself, indicate that he is experiencing a psychological disorder.

As our discussion suggests, the current definition of abnormality depends heavily on social norms and values (see photo). At the same time, societies often have difficulties distinguishing between an abnormality that requires help and an eccentricity that should not be the concern of other people. We often see or hear about people who behave in ways we consider strange, such as an individual who lives alone with dozens of animals and avoids other people. The behaviour of such individuals is deviant, but unless it leads to clear distress and dysfunction, most clinicians would judge it to be eccentric rather than abnormal (Bergner & Bunford, 2017).

An eccentric is a person who deviates from common behaviour patterns or displays odd or whimsical behaviour. Eccentrics do not typically suffer from psychological disorders, and eccentricity is not an absolute but a continuum. Whereas the unusual behaviour of persons with disorders is thrust upon them and usually causes them suffering, eccentricity is chosen freely and provides pleasure. In short, "Eccentrics know they're different and glory in it" (Weeks & James, 1995, p. 14).

Many well-known people were eccentrics. Hetty Green, the richest woman in the world in the late 1800s and early 1900s, always wore the same black dress and only changed her underwear when it wore out. When her son injured his leg, she disguised herself and tried to get him into a charity hospital. Once recognized, she fled with her son, claiming she would treat him herself. He later had to have the leg amputated due to gangrene. Writer

James Joyce always carried a tiny pair of lady's bloomers, which he waved in the air to show approval. Emily Dickinson always wore white, never left her room, and hid her poems in tiny boxes. Benjamin Franklin took "air baths" for his health, sitting naked in front of an open window. United States President John Quincy Adams swam nude in the Potomac River each morning. Canadian Prime Minister William Lyon Mackenzie King regularly attended séances to consult the spirits of Leonardo da Vinci, Sir Wilfrid Laurier, his mother, and several of his Irish Terrier dogs (all named Pat, with the exception of one named Bob) (Dummitt, 2017). Michelangelo, who was notoriously bad-tempered, was also known for his eccentricities: he rarely ate or bathed, slept fully dressed—including his shoes—never changed his clothes, and removed his shoes so infrequently that the skin would often peel off with the shoes. Finally, pop star Lady Gaga was once voted the world's best-loved eccentric celebrity (ABC News, 2012). (See photo.)

Barry Brecheisen/Getty Images

Eccentric? Pop star Lady Gaga said that her former eccentric style, which she recently toned down, was a form of artistic expression.

Do these behaviours constitute mental illness? Most of them probably do not. Although these behaviours disregard standards for normal behaviour, they are largely benign; that is, they are not maladaptive or dysfunctional.

Given such difficulties, how do psychologists determine which experiences constitute or do not constitute a psychological disorder, and how do they distinguish among various disorders? In large part, they rely upon *classification* and *diagnosis*.

Classifying and Diagnosing Psychological Disorders

A symptom is a physical, behavioural, or mental feature that helps indicate a condition, illness, or disorder. Fatigue is often a symptom of depression, for example. Similarly, poor concentration can be a symptom of anxiety, and hallucinations may indicate schizophrenia (Kring & Johnson, 2018; Ernst, 2006). When certain symptoms regularly occur together and follow a particular course, clinicians agree that those symptoms make up a particular mental disorder. A list of such disorders, with descriptions of the symptoms and guidelines for determining when individuals should be assigned to the categories, is known as a *classification system*.

The classification system that is used by most countries throughout the world is the ***International Classification of Diseases (ICD)***, published by the World Health Organization (WHO). The ICD is now in its 11th edition (ICD-11) (Boerma, 2017). The leading classification system in North America is the ***Diagnostic and Statistical Manual of Mental Disorders (DSM)***, published by the American Psychiatric Association. The DSM has been revised several times since it was first published in 1952. The current version is called the DSM-5 (APA, 2013). It lists and describes the symptoms of approximately 22 major categories with more than 200 mental disorders (see **Table 15.1**). Language used in the DSM-5 reflects proposed ICD-11 naming conventions and reflects the collaborative efforts made between the WHO and DSM working groups (Regier, Kuhl, & Kupfer, 2013). However, the process and development of revising the DSM was one of controversy and debate, and the latest manual has not been embraced by all professionals expected to use it. For example, a number of researchers express trepidation, arguing that although conclusive knowledge about the impact of the DSM-5 will come only with time, there are flaws with the manual's content (Wakefield, 2016; Harkness, Reynolds, & Lilienfeld, 2014; Regier et al., 2013; Stein, Lund, & Nesse, 2013). In particular, professionals express concerns about "fuzzy" constructs and narrowly depicted concepts in the DSM-5, as well as a lack of acknowledgement for many of the individual-level and societal-level causal mechanisms known to underlie mental disorders, such as abuse and poverty (Young, 2016). Others contend that the psychiatric drug industry had too strong a role in the development of the latest manual (Cosgrove et al., 2016; Cosgrove & Krimsky, 2012; Frances, 2010).

> ***International Classification of Diseases (ICD)*** the system used by most countries to classify psychological disorders; published by the World Health Organization and currently in its 11th edition (ICD-10).
>
> ***Diagnostic and Statistical Manual of Mental Disorders (DSM)*** the leading classification system for psychological disorders in Canada; DSM-5 is the current version.

When clinicians decide that a person's symptoms fit the criteria for a particular disorder, they are making a **diagnosis**. Most clinicians in Canada use the DSM to help them diagnose their clients' problems. Assigning a diagnosis suggests that the client's pattern of dysfunction is basically the same as patterns displayed by many other people who show the same types of symptoms, has been researched in numerous studies, and has responded to certain kinds of treatment. It helps to ensure that clinicians are acting in a consistent manner and that they are basing their clinical and research decisions on a set of clearly

articulated and shared criteria. Clinicians can then apply what is generally known about the disorder to the client with whom they are working (see Psychology Around Us 15.1).

> **diagnosis** a clinician's determination that a person's cluster of symptoms represents a particular disorder.

As we will see later in this chapter, based on her pattern of symptoms, Diane Markos would probably receive a diagnosis of a mood disorder: *major depressive disorder*. A clinician might also take note of the fact that Diane has avoided people and social relationships throughout her life, largely because she fears being judged, and might further assign her a diagnosis of *avoidant personality disorder*. When people qualify for two or more diagnoses, they are said to display **comorbidity**. Comorbidity refers to the co-occurrence of two or more diagnoses in one person (Sartorius, Holt, & Maj, 2015; Gadermann et al., 2012).

> **comorbidity** the condition in which a person's symptoms qualify him or her for two or more diagnoses.

TABLE 15.1

Disorders in DSM-5

Group	Description	Some Disorders Listed in This Group
Neurodevelopmental disorders	Disorders with their onset in the developmental period before the child enters grade school; usually involve impairments in personal, social, or academic functioning	intellectual disability language disorder autism spectrum disorder specific learning disorder
Neurocognitive disorders	Disorders where the primary clinical deficit is cognitive function. The deficit is acquired in that it reflects a decrease from a previous state of functioning, as in the case of Alzheimer's disease	delirium major and mild neurocognitive disorders major or mild neurocognitive disorder due to traumatic brain injury
Substance-related and addictive disorders	Disorders that involve the activation of reward pathways and reward systems due to substance use or induced by substances; also includes gambling disorder	alcohol use disorder caffeine intoxication opioid use disorder stimulant use disorder

Schizophrenia-spectrum and other psychotic disorders	Disorders defined by abnormalities in the form of delusions, disordered thoughts or behaviours, or negative symptoms such as avolition (lack of motivation) or loss of communication ability	delusional disorder schizophrenia schizoaffective disorder
Depressive disorders	The presence of sad, empty, or irritable mood that typically goes along with physical or cognitive changes	major depressive disorder premenstrual dysphoric disorder disruptive mood dysregulation disorder
Bipolar and related disorders	Alternating bouts of intense positive affect that are followed or preceded by prolonged periods of sadness and other symptoms of depression; seen as a bridge between depressive disorders and disorders representing the schizophrenia spectrum	bipolar I disorder bipolar II disorder cyclothymic disorder
Anxiety disorders	Disorders that share features of excessive fear or anxiety and related behavioural disturbances	specific phobia social anxiety disorder generalized anxiety disorder panic disorder
Obsessive-compulsive and related disorders	Disorders characterized by repetitive thoughts or behavioural rituals	obsessive-compulsive disorder body dysmorphic disorder hoarding disorder
Trauma and stressor-related disorders	Disorders that reflect exposure to a distressing event or events	posttraumatic stress disorder acute stress disorder reactive attachment disorder
Somatic symptoms and related disorders	Disorders with prominent somatic symptoms associated with impairment and distress	somatic symptom disorder conversion disorder factitious disorder

Dissociative disorders	Disruption or discontinuity in the typical integration of consciousness, perception, memory, emotion, identity, or body representation	dissociative amnesia depersonalization/derealization disorder dissociative identity disorder
Feeding and eating disorders	Disturbance in eating or eating-related behaviour that impairs physical health and/or psychosocial functioning	avoidant/restrictive food intake disorder anorexia nervosa bulimia nervosa binge-eating disorder
Sexual dysfunctions	Disorders with great heterogeneity that usually involve a clinically significant disturbance in the ability to respond sexually or experience sexual pleasure	erectile disorder female sexual interest/arousal disorder male hypoactive sexual desire disorder
Gender dysphoria	Persistent distress due to the discrepancy between one's expressed or experienced gender versus the initially assigned gender	gender dysphoria
Paraphilic disorders	Disorders that reflect intense and persistent sexual interest other than the stimulation found in normal physically mature and consenting human partners	voyeuristic disorder frotteuristic disorder sexual sadism disorder
Sleep-wake disorders	Disorders involving dissatisfaction in the quality, timing, and/or amount of sleep	insomnia disorder hypersomnolence disorder narcolepsy central sleep apnea
Disruptive, impulse control, and conduct disorders	Under-controlled behaviours that violate the rights of others and/or bring the person into serious conflict with societal norms or	intermittent explosive disorder conduct disorder kleptomania

	authority figures	
Personality disorders	Pervasive and inflexible behavioural patterns that deviate markedly with societal expectations. These disorders often involve a lack of insight about how personal actions cause distress in others	borderline personality disorder narcissistic personality disorder paranoid personality disorder antisocial personality disorder

15.1 Psychology Around Us

Is a Diagnosis Always Helpful?

Although mental health terms such as anxiety, depression, and schizophrenia are commonly discussed in the media, public discourse, and even daily conversations, it turns out that accurate diagnoses of these and other psychological disorders are often elusive in the clinical field. It appears that even with effective assessment techniques and carefully researched classification categories, clinicians sometimes arrive at a wrong conclusion or diagnosis (Meder & Mayrhofer, 2017; Waldmann & Hagmayer, 2013).

Indeed, studies have sometimes revealed enormous errors in assessment and diagnosis, particularly in hospitals (Mitchell, 2010). In a well-known study assessing the possibility that schizophrenia was over-diagnosed and affective disorders under-diagnosed, the charts of 131 randomly selected patients from a mental hospital in New York were pulled from records and seven skilled clinicians were asked to reevaluate their diagnoses (Lipton & Simon, 1985). Whereas 89 of the patients had originally received a diagnosis of schizophrenia when they were hospitalized, only 16 received this same diagnosis on reevaluation. And while 16 patients initially had been given a diagnosis of mood disorder, 50 received that label on reevaluation, essentially reversing the ratio of schizophrenic to mood disorder.

Furthermore, our society attaches a stigma, or negative prejudice, to mental illness (Crowe, Averett, & Glass, 2016; Seeman, Tang, Brown, & Ing, 2016). Stereotypic beliefs about what it means to have or to have had a mental disorder can mark or stigmatize those currently or previously struggling with a mental disorder. This can make it less likely that they will seek treatment for fear of the stigmatizing consequences (Fox, Smith, & Vogt, 2018). People with such labels may find it hard to get a job, particularly one with a high level of responsibility, or to be accepted socially (Elraz, 2018). In short, such labels may stick for a long time.

Given these problems, some clinicians have argued for doing away with assessment and diagnosis. Others, however, believe that classification and diagnosis are essential to understanding and treating people with psychological difficulties. They suggest that we must simply work to increase what is known about psychological disorders and improve assessment and diagnostic techniques (Corrigan, 2007; Ben-Zeev, Young, &

Corrigan, 2010). On a positive note, a review of interventions aimed at reducing the stigma associated with mental illness in workplace settings suggests that such interventions can improve employee attitudes toward those with a history of mental illness (Hanisch et al., 2016).

Before You Go On

(Answers to Before You Go On may be found online in the Course Resources.)

What Do You Know?

1. Define and explain the "four Ds" of abnormal behaviour.

2. What is the DSM-5?

What Do You Think? • In this section, we talked about the stigmatizing issues associated with being diagnosed with a mental disorder. Think about people you know or people you have heard about or read about who were described as "having a mental disorder." What sorts of things did you think or assume about them simply based on this knowledge? Any negative generalizations could become part of the stigma associated with mental disorders.

Models of Abnormality

LEARNING OBJECTIVE 2

Describe the major models used by psychologists to explain abnormal functioning.

The perspectives that scientists use to explain phenomena are known as *models*, or *paradigms* (Kuhn, 1962). You can think of a model or paradigm as a big idea about how things work. So, for example, a mechanistic paradigm builds on the idea that people are like complex machines and then when something goes wrong, it is probably because something in the mechanism is broken. To understand how a clinical theorist explains disorders, we must know which model shapes the theorist's view of abnormal functioning. Thus, in this section we will examine today's most influential clinical models—the neuroscience, psychodynamic, cognitive-behavioural, humanistic-existential, socio-cultural, and developmental psychopathology models (see Table 15.2). In the next chapter, we will see how these models inform treatment.

TABLE 15.2

Today's Leading Models of Abnormality

Approaches	Causes of Abnormal Functioning
Neuroscience	Structural or biochemical malfunctions in the brain

Approaches	
Psychodynamic Approaches	Unconscious conflicts often rooted in childhood
Cognitive-Behavioural Approaches	Abnormal behaviours acquired through a tightly interwoven mix of conditioning, modelling, and cognitive principles
Humanistic and Existential Approaches	Distorted views of self that prevent personal growth or decision making
Socio-cultural Approaches	Societal, cultural, social, and family pressures or conflicts
Developmental Psychopathology Approach	Early risk factors combined with poor resilience throughout life stages

The Neuroscience Model

Neuroscientists view abnormal behaviour as an illness brought about by a malfunctioning brain (Pliszka, 2003). As we have seen throughout the textbook, researchers have discovered connections between certain psychological or neurological disorders and problems in specific structures of the brain. Neuroscientists have also linked some mental disorders to deficient or excessive activity of different neurotransmitters. Depression, for example, seems to be associated with insufficient activity of the neurotransmitters *norepinephrine* and *serotonin* (Beck & Alford, 2009; Blier, 2016). In addition to focusing on neurotransmitters, neuroscience researchers have learned that mental disorders are sometimes related to abnormal hormonal activity in the body's endocrine system. Abnormal secretions of the hormone *cortisol*, for example, also have been tied to depression (Qin et al., 2016; Vrshek-Schallhorn et al., 2013).

AP Photo/M. SPENCER GREEN

Extreme antisocial disorders and the brain **Forensic psychiatrist Helen Morrison displays slices of the brain of John Wayne Gacy, who murdered at least 33 boys and young men between 1972 and 1978. Post-mortem examinations have not revealed clear links between abnormal brain structure and the extreme antisocial patterns exhibited by Gacy and other serial killers.**

What causes these problems with brain anatomy and chemical functioning (see photo)? Two factors have received particular attention from clinical theorists in recent years: *genetics* and *viral infections*.

Studies suggest that genetic inheritance plays a key role in mood disorders, schizophrenia, intellectual disability, Alzheimer's disease, and other mental disorders. It appears that in most cases, no single gene is responsible for a particular disorder (Coleman et al., 2020; Uher & Zwicker, 2017). Instead, many genes combine to help produce our actions and reactions, both functional and dysfunctional. Moreover, as you have read throughout the textbook, the predispositions set up by such genes often will result in psychological disorders only when the individuals are also exposed to adverse environmental conditions.

Another possible source of abnormal brain structure or biochemical dysfunction appears to be viral infections. Some research suggests, for example, that schizophrenia, a disorder marked by hallucinations and other departures from reality, may be related to exposure to certain viruses before birth or during childhood (Torrey & Yolken, 2017). The studies suggest that a damaging virus may enter the brain of a fetus or young child and then remain quiet there until the individual reaches puberty or young adulthood. At that time, activated

by hormonal changes, by another infection, or by stressful life events, the virus may set in motion the symptoms of schizophrenia. In addition to schizophrenia, research has sometimes linked viruses to mood and anxiety disorders (Torrey & Yolken, 2017). Exposure to traumatic events early in childhood has also been linked to the later onset of symptoms of schizophrenia (Stilo & Murray, 2019).

Today, the neuroscience model for understanding mental dysfunction is highly regarded, and researchers are rapidly identifying valuable new information about various psychological and neurological disorders (Rodgers et al., 2017; Littrell, 2015). As you will see in Chapter 16, drug treatments and biological interventions such as psychotropic medications or electroconvulsive therapy (ECT) often bring great symptomatic relief where other approaches have failed.

At the same time, some proponents of the neuroscience model seem to expect that biological factors and brain interventions alone can explain and treat all abnormal behaviours. However, to better understand mental health and mental illness we need to avoid dependency on *reductionist perspectives* that attempt to reduce complex phenomenon to a single cause (Bulut, Gursoy, & Sayar, 2020). Reductionist views such as biomedical models neglect the complex interplay of biological and non-biological factors, including a person's environmental experiences. Indeed, as we have seen throughout this book, the connections in our brains unfold partly in response to the experiences that we keep having throughout our lives, beginning in the womb.

So, since we know that the mind affects the body and that the body also affects the mind, we must come to understand the complex interactions between the biological, social, psychological, and cultural variables present in the lives of all individuals. The *biopsychosocial perspective*, first identified by George Engel (1980, 1977), recognizes the links between each of these important areas of human development (Wade & Halligan, 2017). The biological component involves a focus on genetic and epigenetic factors as well as biochemical influences and differences in brain structure and function. The psychological component includes interpersonal interactions, personality variables, cognitive and learning histories and development, attitudes, and ability to cope. The social component considers socialization experiences, cultural and social interactions and variables, and life experiences. When studying mental illness, the focus is on how these variables interact to produce the behaviours being treated. However, this model can be employed for describing typical development as well.

The notion that disorders arise from an interaction of internal and external causes resulted in a model known as the *diathesis-stress model*. This model suggests that a person may inherit a genetic predisposition (a diathesis) for a disorder, but that it will remain undeveloped unless triggered by an external (stressful) life event. So, for example, you and your brother may have both inherited a predisposition for depression. However, he is in a serious car accident where two of his childhood friends are killed; he feels terrible guilt for surviving this accident, and his capacity to cope is exceeded. You experience nothing like this. Your brother develops depression and you do not. Of course, we have to also consider that individuals respond to stressful events with quite different trajectories. That is to say, you may have experienced the same adverse event as your brother, but might have responded quite differently and thereby would not have triggered a psychiatric disorder (Monroe & Cummins, 2014).

Neuroscience and the *Diagnostic and Statistical Manual* (DSM) and *International Classification of Diseases* (ICD)

The discoveries of drugs that affected the symptoms of mental disorders, as will be discussed in Chapter 16, gave a strong push to the idea that mental disorders are, at least in part, brain-based and reflect ways in which our neurochemistry relates to our adaptive, and sometimes to our maladaptive, behaviour. Despite this, the role that neuroscience research has played in the development of the criteria and manuals for diagnosing—the *Diagnostic and Statistical Manual* (DSM) and *International Classification of Diseases* (ICD)—and the plans for treating mental disorders has been limited (Cuthbert, 2014; Kozak & Cuthbert, 2016). The work on the new edition of the DSM (DSM-5), for example, was conducted by large committees of clinicians and clinical researchers working in each diagnostic area of the manual. While there has been acknowledgement that it would be of great benefit to have clearer neurological assessment tools and research mapping the brain-based links of symptom patterns associated with one or more diagnostic category, it is generally felt that neuroscience has not yet provided needed clarity for sharp diagnostic decisions. In other words: We just need more research. The problem, as stated by Thomas Insel, the former director of the American National Institute of Mental Health, is that research-granting criteria and reviewing standards are based on the existing diagnostic categories of the DSM and ICD. This means that funded neuroscience research was not providing the knowledge and diagnostic and treatment guidelines needed to develop a neuroscience foundation for understanding and treating mental disorders.

The proposed solution is called the Research Domain Criteria (RDoC) project, which is intended to "foster research to validate dimensions defined by neurobiology and behavioral measures that cut across current disorder categories, and that can inform future revisions of our diagnostic systems" (Cuthbert, 2014, p. 29). Essentially this means looking at what we know about how the brain is systemically organized and then looking to see how brain functioning at different levels in each of those systems can help us to better understand both "normal" and abnormal thoughts and behaviour. The Research Domain Criteria model is shown in **Table 15.3**. In it you can see the areas or systems of brain functioning down the left side and the types of desired research analysis aimed at better understanding each area laid out across the top.

TABLE 15.3

Cognitive (effortful) control
Systems for Social Processes
Affiliation/attachment
Social communication
Perception/understanding of self
Perception/understanding of others
Arousal/Modulatory Systems
Arousal
Biological rhythms
Sleep-wake

By beginning with a neuroscience perspective on the various brain systems and working toward an understanding of adaptive and abnormal behaviour, the RDoC is not limited by being applied only within already agreed upon diagnostic categories, though it could be of use in sorting out subtypes or variations of symptom patterns in disorder categories. For example, PTSD is regarded as very clearly a “fear circuit” disorder. Despite this, some patients have “blunted” emotional responses and do not show the expected fear reactions. Different therapy approaches work for fear-reactive as opposed to emotionally blunted individuals. The RDoC model would suggest the development of an assessment tool for emotional responsiveness in order to test therapy responsiveness and eventually, perhaps,

to ensure that diverse PTSD patients quickly get the appropriate therapy for their version of the disorder (Grant et al., 2020).

The potential impact of the RDoC on neuroscience research related to abnormal behaviour and the identification, diagnosis, and treatment of mental disorders is huge, especially given the millions of dollars in research funding given out each year by the U.S. National Institute of Mental Health. If you are interested in where some possible big changes in abnormal and clinical psychology are going to come from in the next few years, this is a good area to watch (Sanislow et al., 2019).

The Cognitive-Behavioural Model

Cognitive-behavioural theorists propose that psychological disorders result largely from a combination of problematic learned behaviours and dysfunctional cognitive processes. According to this model, such behaviours and thinking processes interact with and mutually influence each other: people use their particular ways of thinking to explain their behaviours and the events in their lives, behaviours may lead to particular thoughts, various cognitions may trigger certain behaviours, and so on. Cognitive-behavioural theorists also view emotions and biological events as key variables. And, indeed, they seek to understand how these variables influence and interact with behaviours and cognitions to help bring about abnormal functioning. Both behavioural and cognitive principles lie at the centre of the model (Friedman, Koenig, & Thase, 2016; Butler et al., 2006). Correspondingly, as you will see in Chapter 16, cognitive-behavioural therapists focus largely on behaviours and cognitions in their efforts to help people with psychological disorders by helping them to change their thoughts and behaviours.

To more fully understand the cognitive-behavioural model, it is useful to first examine the behavioural and cognitive components separately. In fact, at one time, the behavioural model stood alone, and behaviourists used only principles of conditioning and modelling to explain abnormal functioning. In the 1960s, however, a number of theorists began calling for a more cognitive-behavioural perspective (Beck, 1975). They argued that human beings engage in unseen *cognitive behaviours*, such as private thoughts and beliefs, and that people's cognitions greatly influence and are influenced by their behaviours.

The Behavioural Perspective

As we observed in Chapter 7, behavioural theorists use learning principles to explain human functioning. These principles focus on how the environment changes a person's behaviours. Many learned behaviours are constructive and help people to cope with daily challenges and lead satisfying lives. However, abnormal and undesirable behaviours also can be learned.

According to the behavioural perspective, abnormal behaviours are acquired by the same principles of learning as adaptive behaviours. As you saw in Chapter 7, for example, phobias may occur as a result of *classical conditioning* when a previously neutral object becomes paired with an unconditioned stimulus that creates fear (see photo).

©AP Images/CHRISTOPHER A. RECORD

"Virtual" desensitization Virtual reality software enables phobic clients to more vividly experience their feared objects and situations, such as flying in an airplane, during desensitization.

Behavioural theorists also suggest that some of the many behaviours we learn through *operant conditioning* processes of reward and punishment are abnormal ones. For example, some people may learn to abuse alcohol and drugs because initially such behaviours brought feelings of calm, comfort, or pleasure. Others may develop or continue to display disordered eating patterns partly because of praise they receive for a thinner appearance or because of the comfort eating certain foods provides them (Gibson, 2012; Wilson, 2011).

Modelling, in which we learn by observing others, can also lead to abnormality. Recall from Chapter 7 the famous study in which children learned from a model to behave aggressively toward a Bobo doll, an inflatable clown (Bandura, Ross, & Ross, 1963). Similarly, children of psychologically dysfunctional people may develop maladaptive reactions because of their exposure to the models presented by their parents (O'Neal et al., 2016; Rossman, Hughes, & Rosenberg, 2013; Luyckx et al., 2011).

One of the appeals of behavioural principles is that, in contrast to psychodynamic concepts, they can be tested in the laboratory. Experimenters have used the principles of conditioning to produce clinical symptoms in research participants, suggesting that psychological disorders may in fact develop through learning (Morris, Rumsey, & Cuthbert, 2014). Moreover, as you will see in Chapter 16, research has indicated that behavioural interventions can be helpful to people with specific fears, compulsive behaviours, social deficits, intellectual disabilities, and a wide range of other problems (Wilson, 2011).

The Cognitive Perspective

According to the cognitive perspective, when people display abnormal patterns of functioning, cognitive problems are to blame. Abnormal functioning can result from several such problems, including *maladaptive beliefs* and *illogical thinking processes* (see photo).

Colin Hawkins/Cultura/Getty Images

Cognition and psychological disorders **Social isolation and difficulties in problem solving can make it harder for people to get help with depression.**

The pioneering clinical theorists Albert Ellis (1913–2007) and Aaron Beck proposed that each of us holds broad beliefs about ourselves and our world that help to guide us through life and determine our reactions to the situations we encounter. However, some people's beliefs are unjustified and unhelpful, leading them to act and react in ways that are inappropriate and that reduce their chances of happiness (Barth, 2014; Beck & Haigh, 2014).

Such people may, for example, assume that they are failures if they are not loved or approved of by every person they know. An otherwise successful presentation in the classroom can, for example, make them sad or anxious because one listener seemed bored. Their problematic belief helps set the stage for a life hampered by tension and disappointment.

Think back to Diane Markos, whose case opened this chapter. She held some unjustified beliefs that may have left her particularly vulnerable to depression. Her case study further stated:

> *Many of her [problems] seemed to stem from underlying attitudes . . . such as: "If I care for others, they should/must care for me," or "If something good happens to me, I'll have to pay for it later with pain," or "People either love me or hate me"* (Spitzer et al., 1983, p. 129).

As is discussed in Chapter 16, Beck also found that some people continuously think in illogical ways and keep drawing self-defeating and even pathological conclusions (Beck & Weishaar, 2011). He identified several illogical thinking processes—processes that turn out

to be very common in depression and anxiety disorders. These include:

Selective perception—seeing only the negative features of an event.

Magnification—exaggerating the importance of undesirable events.

Overgeneralization—drawing broad negative conclusions on the basis of a single insignificant event.

Diane Markos's therapist noted repeated examples of illogical thinking that helped predispose Diane to depressive reactions:

> *When she finally did get a B from her professor, she concluded that she had failed miserably. There was no recognition of any middle ground between total academic success and total academic failure. Moreover, she tended to magnify the importance of events like this as if they were an indictment of her as a total human being* (Spitzer et al., 1983, p. 129).

The cognitive perspective has appealed to a wide range of theorists. They embrace a viewpoint that sees *thought* as a key factor in both normal and abnormal behaviour. Research supports this appeal. Investigators have found that people with psychological disorders do, indeed, often display the kinds of beliefs and errors in thinking described in the cognitive theories (Gellatly & Beck, 2016; Sharf, 2012; Buschmann et al., 2018). The cognitive perspective provides ways to challenge such negative beliefs and cognitive errors and thus to reduce stress and increase happiness. Parts of this have contributed to the development of Positive Psychology, though recently there have been some suggestions and some research into the need for a New Positive Psychology (PP 2.0) which moves beyond the simpler "happiness is good" approach to a more nuanced "embrace the challenges" approach. Find out about this be reading Positive Psychology 15.1.

The Psychodynamic Model

The psychodynamic model has its roots in Sigmund Freud's theories. As we observed in Chapter 12, psychodynamic theorists believe that a person's behaviour is determined largely by underlying psychological forces of which the person is not consciously aware. Abnormal behaviours or symptoms are viewed as the consequences of conflicts between these forces or as unconscious attempts to resolve conflicts and lessen painful inner turmoil.

Fancy/Veer/Corbis/Getty Images

Anal personality? According to Freud, when an individual's neat and orderly personality is as extreme as this woman's (prior to storing her knickknacks, she organizes them carefully before her and enters each item on a computer file), fixation at the anal stage of development may be operating.

As we pointed out in Chapter 12, Freud proposed that a child's environment may prevent his id, ego, and superego from maturing properly or interacting effectively. When that happens, the child can become *fixated*, or entrapped, at an early stage of development. Such fixations affect all subsequent development and may set in motion abnormal functioning (see photo).

Freud would have suggested that the family pressures Diane Markos experienced during her early years caused an imbalance of power among her id, ego, and superego. The demands she experienced forced her to put aside many of her own id needs and to act in a mature, ego-dominated manner beyond her years. Freud would certainly have looked upon such childhood pressures and deprivations as possible roots for her adult depression.

15.1 Psychology Around Us | Positive Psychology

The Second Wave of Positive Psychology

Throughout this book you have read about a relatively new field of psychology: positive psychology. However, it has not been without controversy. Over the last several decades, critics of this field have highlighted the need for a more balanced, or nuanced, approach to how we perceive positive and negative qualities, especially regarding how our perception of these qualities affects our understanding of mental health—especially mental illness. For example, optimism can be seen as a positive trait that all of us may want. However, in certain cases of attention deficit/hyperactivity disorder, the verbalizing and setting of overly optimistic goals may actually be a negative, not positive, aspect of optimism (Knouse & Mitchell, 2015). Optimism in bipolar disorder, specifically the mania phase, may also be biased toward an overly optimistic belief of future events that is not realistic, and may actually be harmful

(Schönfelder, Langer, Schneider, & Wessa, 2017). Perhaps the idea that all positive traits are good and improve life all of the time needs to be re-thought.

Recently, a second wave of positive psychology, known as PP 2.0, has emerged from this sort of re-thinking; perhaps acknowledging that life is sometimes not so positive is not a bad thing. PP 2.0 has implications for both how we view mental illness and how we view the contributions of positive psychology to counselling psychology. It has been argued that there is courage in accepting that life is made up of both good and bad elements and also that we can learn from Indigenous psychology, which tries to find deep joy in bad situations (Wong, 2019). Some examples of PP2.0 research include; the finding that people who hotly pursue happiness are more likely to be more depressed, miserable, and unhappy (Gruber, Mauss, and Tamir, 2011) and suffering and psychological pain are most effectively addressed not by ignoring it but, rather, by accepting it and transforming its meaning (López-Solà, Koban, & Wager, 2018). PP 2.0 is looking at the long term value in embracing the darker sides of human existence and wrestling with our ultimate concerns (Wong, 2019). Margaret Trudeau's book *Changing My Mind* addresses in part this dialectic between the good and bad aspects of traits such as optimism that all individuals, those with and those without a mental illness, must face (Lomas & Ivtzan, 2016).

Zyn Chakrapong/Shutterstock

Positive and negative qualities **Accepting that life is made up of both negative and positive elements that affect our mental health may have long-term value when it comes to facing a mental illness and the challenges it can bring to a person's life.**

As we also saw in Chapter 12, several of Freud's colleagues disagreed with key aspects of his theories. As a result, there are now a number of different psychodynamic explanations for abnormal functioning (Sharf, 2012). For example, one group of psychodynamic theorists, called *object relations* theorists, believes people are motivated primarily by a need to establish relationships with others, known as *objects* (see photo). They propose that severe problems in early relationships may result in abnormal development and psychological problems (Phares, 2020; Guntrip, 2018; Huprich et al., 2017).

Pepsco Studio/Shutterstock

Setting the stage **Object relations theorists believe that early relationships in life, particularly with parents, are key to adult functioning.**

Freud and his followers helped change the way abnormal functioning is viewed (Wolitzky, 2011). Primarily because of their work, many different kinds of theorists today look for explanations outside biological processes. In addition, Freud and his followers were the first practitioners to demonstrate the value of systematically applying theory and techniques to treatment. However, as you will see in Chapter 16, research has often failed to support the effectiveness of psychodynamic therapies (Prochaska & Norcross, 2010).

The Socio-Cultural Model

According to many theorists, abnormal behaviour is best understood in light of the social, cultural, and family forces brought to bear on an individual. The unique characteristics of a given society may create special stresses that heighten the likelihood of abnormal functioning in its members. Researchers have, for example, found relationships between abnormal functioning and factors such as widespread social change, socio-economic class membership, cultural background, social networks, and family systems (Kirmayer, Gomez-Carrillo, & Veissière, 2017; Ventriglio, Gupta, & Bhugra, 2016).

Social Change

When a society undergoes major change, the mental health of its members can be greatly affected. Societies undergoing rapid urbanization, for example, usually show a rise in mental disorders (Anakwenze & Zuberi, 2013). It is not yet known which features of urbanization—overcrowding, technological change, social isolation, migration, and so forth

—are most to blame. Similarly, societies in the throes of economic depression often display rises in rates of clinical depression and suicide (Miret et al., 2013).

Socio-economic Class

Studies by Jitender Sareen, Brian Cox, and Murray Stein at the University of Manitoba have found that rates of psychological abnormality, especially severe abnormality, are much higher among members of the lower socio-economic classes than among members of the higher ones (Keyes et al., 2014; Sareen et al., 2011). Perhaps the special pressures of lower-class life help explain this relationship. Poverty is linked to many stressors, including high rates of crime, unemployment, overcrowding, and even homelessness, as well as inferior medical care and limited educational opportunities (see photo). Of course, other factors may account for this relationship. People who suffer from significant mental disorders may be less effective at work, earn less money, and, as a result, drift downward to settle in a lower socio-economic class (Tiikkaja et al., 2016; Sayeed & Fernando, 2018; Lee et al., 2020).

ROMEO RANOCO / REUTERS/ADOBE STOCK

The economy and mental health **Thousands of Filipino job seekers line up at a 2009 job fair in Manila. Unemployment and poverty are strongly linked to psychological dysfunction.**

Cultural Factors

Many theorists believe that human behaviour, including abnormal behaviour, is understood best by examining an individual's unique cultural context, including the values of that culture and the external pressures faced by members of the culture (Matsumoto & Juang, 2016; Duarte et al., 2020a; 2020b; Alegría et al., 2018). As we have seen throughout this book, the cultural groups that have been studied most often are ethnic and racial minority groups, along with economically disadvantaged persons, women, and LGBTQ+ individuals

(see photo). Each of these groups faces special pressures in society that may help produce feelings of stress and, in some cases, abnormal functioning. Moreover, of course, membership in these groups often overlaps.

Kevin Mazur/One Love Manchester/Getty Images

Pressures of discrimination **In June 2017, Ariana Grande performed a benefit concert for victims of the suicide terrorist bombing of her concert in Manchester, England. Multicultural research suggests that prejudice and discrimination can contribute to abnormal functioning.**

Researchers have learned that women are at least twice as likely as men to be diagnosed with depressive and anxiety disorders, although this may be due partially to women being more likely than men to seek treatment (Brown, Sagar-Ouriaghli, & Sullivan, 2019; Seidler et al., 2016; Yousaf, Grunfeld, & Hunter, 2015). Suicide rates in the Canadian Indigenous population are more than twice the overall rate and three times the age-specific rates of non-Indigenous Canadians (24.3 deaths per 100,00 among First Nations people, which is three times the general population rate of 8.1 deaths per 100,000; 14.7 deaths per 100,000 among Metis people; and 72.3 deaths per 100,000 among Inuit people) (Kumar & Tjepkema, 2019). Indigenous Canadians also display extremely high alcoholism rates (Lemstra et al., 2013). In Canada, cultural origins, immigrant status, and Indigenous status have been linked to varying rates of mental illness and adjustment issues (Boksa, Joober, & Kirmayer, 2015; Kirmayer & Valaskakis, 2009). Racial and sexual prejudice and related problems certainly may help explain these differences (Reading & de Leeuw, 2014; Goodman et al., 2017).

A good example of the role of culture in mental health comes from the work of Michael Chandler (University of British Columbia) and Chris Lalonde (University of Victoria). They examined the youth suicide rates among a large number of First Nations band communities in British Columbia. In addition to suicide rates, Chandler and Lalonde gathered data regarding whether each band was or had been engaged in land claim negotiations with the

provincial government; whether the band had taken control of education, fire, police, and child welfare services in their community; and whether there was a physical structure in the community dedicated to their cultural heritage. Their results indicate that if all of these factors were in place, the youth suicide rate was among the lowest in Canada; if none of them were in place, the rates were among the highest in Canada (Chandler & Lalonde, 2019; Chandler et al., 2003; Chandler & Proulx, 2008). These results suggest that having a strong, culturally rich context in which to develop has a significant positive effect on individual mental health and identity development.

Another cultural factor that has received much attention from clinical researchers and therapists in recent years is religion. Researchers have studied possible links between religious faith and mental health, and have learned that the two are often correlated. Studies have found, for example, that genuinely spiritual people tend, on average, to be less lonely, pessimistic, depressed, or anxious than other people (Underwood, 2011). Moreover, as we observed in Chapter 14, such individuals often seem to cope better with major life stressors and appear less likely to abuse drugs or to attempt suicide. Spirituality can be a source of comfort, hope, and meaning, which may at least partially account for this spirituality effect (McClintock, Lau, & Miller, 2016; Koenig, 2012).

Social Networks and Supports

Many theorists focus on the social networks in which people operate, including their social and professional relationships. How well do they communicate with others? What kind of signals do they send to or receive from others? Researchers have often found ties between deficiencies in a person's social networks and that person's functioning (Liu, Gou, & Zuo, 2016; Lee, Chung, & Park, 2016; Santini et al., 2016; Bryant et al., 2016). They have observed, for example, that people who are isolated and lack social support or intimacy in their lives are more likely to become depressed when under stress and to remain depressed longer than are people with supportive spouses or warm friendships. Some recent research indicates that for adolescents and young adults, social media may provide a conduit for social connections that helps them deal with mental health issues (Singleton, Abeles, & Smith, 2016; Best, Manktelow, & Taylor, 2016).

Family Systems

According to **family systems theory**, the family is a system of interacting parts—the family members—who interact with one another in consistent ways and follow rules unique to each family (Keller & Noone, 2019; Goldenberg & Goldenberg, 2011). Family systems theorists believe that the *structure* and *communication* patterns of certain families actually force individual members to react in ways that otherwise seem abnormal. If the members were to behave normally, they would severely strain the family's usual manner of operation and would actually increase their own and their family's turmoil.

> **family systems theory** a theory holding that each family has its own implicit rules, relationship structure, and communication patterns that shape the behaviour of the individual members.

Recall, for example, how Diane Markos's family was structured. She was required to be a

third parent in the family, which in many ways deprived her of normal childhood experiences and emotions. In turn, she came to view her life as one of "servitude, rejection, and failure," and she experienced ongoing depression.

The Developmental Psychopathology Model

Developmental psychopathology is an area that is interested in how psychological disorders evolve, based on both genetics and early childhood experiences. Researchers interested in this area try to understand how early problematic patterns affect functioning as individuals move through later life stages (Cicchetti & Toth, 2016; Leventhal et al., 2016; Cicchetti, 2016; Hinshaw & Beauchaine, 2017). Developmental psychopathologists compare and contrast abnormal behaviour patterns with more typical ones, attempting to identify **risk factors**—biological and environmental factors that contribute to negative outcomes. In addition, they seek to identify other factors that can help children avoid or recover from such outcomes.

> **developmental psychopathology** the study of how problem behaviours evolve as a function of a person's genes and early experiences, and how these early issues affect the person at later life stages.
>
> **risk factors** biological and environmental factors that contribute to problem outcomes.

Like other developmental psychologists, developmental psychopathologists hold that behaviour can be analyzed in a variety of ways. A full accounting of how individuals get off-track (or stay on-track) requires looking at how genetics, early environmental influences, and their own psychological processes all collaborate to form their current pattern and functioning.

Developmental psychologists have contributed two concepts to the field of psychology: *equifinality* and *multifinality* (Oshri et al., 2017; Barrett, 2019). The concept of **equifinality** holds that individuals can start out from a variety of different places and yet, through their life experiences, wind up functioning (or dysfunctioning) in similar ways. **Multifinality** follows the opposite principle. It suggests that children can start from the same point and wind up in any number of different psychological places.

> **equifinality** the idea that different children can start from different points and wind up at the same outcome.
>
> **multifinality** the idea that children can start from the same point and wind up at any number of different outcomes.

Let's apply these two concepts to *conduct disorder*, a disorder of childhood and adolescence characterized by repeated violations of others' rights, displays of aggression, and destructive behaviour. A child with this disorder may have been born with a difficult temperament, experienced poor parenting, or developed poor social skills (Vaughn, Salas-Wright, DeLisi, & Maynard, 2014; Ronan et al., 2016). As suggested by the notion of *equifinality*, regardless of which set of those risk factors is at play, in the beginning the

outcome is the same, in this case, conduct disorder. At the same time, *multifinality* would predict that not every difficult child and not every child with ineffective parents will wind up with a conduct disorder. The vast majority will wind up with no pathology at all. So children with similar beginnings can end up in very different places.

Developmental psychopathologists are very interested in the biological, psychological, or environmental events that help buffer against or negate the impact of risk factors—events that help produce **resilience**, an ability to recover from or avoid the serious effects of negative circumstances (Cicchetti, 2016; Dudley et al., 2011; Flouri et al., 2011). In short, according to this viewpoint, it is more important to understand what goes right than it is to understand what goes wrong.

resilience the ability to recover from or avoid the serious effects of negative circumstances.

Before You Go On

(Answers to Before You Go On may be found online in the Course Resources.)

What Do You Know?

3. What are the major models used by psychologists to explain abnormal functioning?

4. What major types of brain problems are linked to abnormal functioning?

5. In the view of cognitive-behavioural theorists, what kinds of problems can lead to abnormal functioning?

6. How are the humanistic and existential models similar, and how do they differ?

7. What social and cultural factors have been found to be related to abnormal functioning?

What Do You Think? • How would you describe your personal model for explaining why people behave as they do?

Mood Disorders

LEARNING OBJECTIVE 3

Describe and differentiate major depressive disorder and bipolar disorder.

As you saw earlier, there are more than 200 different disorders listed in DSM-5. In the rest of this chapter, we will look at some of the disorders that are particularly common and that have received considerable study. We begin with mood disorders. Moods are temporary, non-specific emotional states. Mood disorders are mental disorders characterized by pervasive disturbed mood as the dominant feature. There are two primary types of mood disorder: unipolar mood disorder, also called depression, and bipolar disorder, where

people move between one extreme mood state to another (see photo).

PeopleImages/Getty Images

Mood disorders In mood disorders, individuals experience either unipolar mood disorder (where they experience depression) or bipolar disorder (where they move from one extreme mood state to another).

Depression and mania are the key features in mood disorders. **Depression** is a low, sad state in which life seems dark and hopeless and its challenges seem overwhelming. **Mania**, the opposite of depression, is a state of breathless euphoria, or frenzied energy, in which people may have an exaggerated belief that the world is theirs for the taking. Most people with a mood disorder suffer only from depression, a pattern found in **major depressive disorder** or in a less disabling but chronic form of depression called Persistent Depressive Disorder (dysthymia). Others experience periods of mania that alternate or intermix with periods of depression, a pattern called **bipolar disorder** in its severe form and *cyclothymic disorder* in a less severe but chronic form (Frank & Michael, 2013; Beck & Bredemeier, 2016).

depression a persistent sad state in which life seems dark and its challenges overwhelming.

mania a persistent state of euphoria or frenzied energy.

major depressive disorder a disorder characterized by a depressed mood that is significantly disabling and is not caused by such factors as drugs or a general medical condition.

bipolar disorder a mood disorder in which periods of mania alternate with periods of depression.

Major Depressive Disorder

People more unhappy than usual often say they are “depressed.” Typically, they are

responding to sad events, fatigue, or unhappy thoughts. This use of the term confuses a perfectly normal mood swing with a clinical syndrome. All of us experience dejection from time to time; few of us experience major depressive disorder. This disorder brings severe and long-lasting psychological pain that may intensify as time goes by. Those who suffer from it may become unable to carry out the simplest of life's activities. Some even try to end their lives.

It is estimated that nearly 8 percent of adults in Canada are diagnosed with major depressive disorder in any given year. Another 3 percent of adults are diagnosed with mild forms of the disorder (Canadian Mental Health Association, 2014b; Mental Health Commission of Canada, 2013). Women are at least twice as likely as men to be diagnosed with depression. It is important to note that this difference between men's and women's rates of depression could reflect a number of factors, such as women's greater tendency to seek assistance; men's tendency to deny or pay less attention to their feelings; and women's greater likelihood of carrying the stress of multiple roles as parent, spouse, and employee. These factors can lead to differential diagnosis rates, without telling us about the actual underlying rates of disorders like depression among men and women (Salk, Hyde, & Abramson, 2017; Yoon & Kim, 2018). Approximately half of people with this disorder recover within six weeks, and 90 percent recover within a year, some without treatment (Klein & Allmann, 2015). However, most of them have at least one other episode of depression later in their lives (Bukh, Andersen, & Kessing, 2016; Fuller-Thomson, Agbeyaka, LaFond, & Bern-Klug, 2016).

TABLE 15.4

The Diagnostic Criteria for a Major Depressive Episode from the DSM-5
Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition. Copyright ©2013 American Psychiatric Association.

Major Depressive Episode
A. Five (or more) of the following 9 symptoms have been present during the same two-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.
B. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
C. The episode is not attributable to the physiological effects of a substance or to another medical condition.
(1) Depressed mood most of the day, nearly every day, as indicated by either subjective report (e.g., feels sad or empty) or observation made by others (e.g., appears tearful) *Note:* In children and adolescents, can be irritable mood.
(2) Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation made by others)
(3) Significant weight loss when not dieting or weight gain (e.g., a change of more than 5%

of body weight in a month), or decrease or increase in appetite nearly every day *Note:* In children this may be a failure to make expected weight gains.
(4) Insomnia or hypersomnia nearly every day
(5) Psychomotor agitation or retardation nearly every day (observable by others)
(6) Fatigue or loss of energy nearly every day
(7) Feelings of worthlessness or excessive or inappropriate guilt nearly every day
(8) Diminished ability to think or concentrate, or indecisiveness, nearly every day
(9) Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide

The DSM-5 diagnostic criteria for a major depressive episode are listed in **Table 15.4**. Due to space limitations, we have not included the DSM diagnostic criteria for the other disorders we discuss in this chapter. If you are interested in reviewing the diagnostic criteria for other disorders, search online using the following terms: DSM-5 criteria for "name of disorder." This search will return many websites showing the DSM diagnostic criteria for the disorder in question. Make sure that the site you choose to view clearly states that the criteria it displays are from the DSM (the most recent version is the DSM-5) and that the site references the DSM as the source of the material. That way you can be reasonably confident that the criteria being shown are accurate.

Hans Neleman/Getty Images

Feeling blue **Feeling sad is not necessarily depression. Major depressive disorder brings severe and long-lasting psychological pain that may intensify as time goes by.**

As we saw in the case of Diane Markos, severe depression has many symptoms other than sadness, and the symptoms often feed into one another. The symptoms span five areas of functioning: emotional, motivational, behavioural, cognitive, and physical.

Characteristics of Depression

Most people who are depressed feel sad and dejected (see photo). They describe themselves as "miserable" and "empty." They often lose the desire to participate in their usual activities. Almost all report a lack of drive, initiative, and spontaneity. Many depressed people become uninterested in life or wish to die; others wish that they could kill themselves, and some actually try. Suicide represents the ultimate escape from life's activities and pressures. It has been estimated that between 6 and 16 percent of people who suffer from severe depression commit suicide (De Leo & San Too, 2014; Laursen et al., 2016).

Depressed people are usually less active and less productive than other people. They spend more time alone and may stay in bed for long periods. They may also move and even speak more slowly than others. Most hold extremely negative views of themselves. They consider themselves inadequate, undesirable, inferior, and perhaps evil. They also blame themselves for nearly every unfortunate event (Lakey et al., 2014). Another cognitive symptom of depression is pessimism. Sufferers are usually convinced that nothing will ever improve, and they feel helpless to change any aspect of their lives (Pu, Hou, & Ma, 2016; Tuckwiller & Dardick, 2018). Finally, people who are depressed often have physical ailments such as headaches, indigestion, constipation, dizzy spells, and general pain. They may also have disturbances in appetite and sleep (Bekhuis et al., 2016; Schaakxs et al., 2017).

Major depressive disorders often seem to be triggered by stressful events (Park et al., 2019; Kendler & Gardner, 2016). (See Psychology Around Us 15.2.) In fact, researchers have found that depressed people experience a greater number of stressful life events during the month just before the onset of a depressive episode than do other people during the same period of time (Kendler & Gardner, 2016; Monroe, Anderson, & Harkness, 2019). However, it is important to remember that stress is not just something that happens *to* us. For instance, Kate Harkness and her associates at Queen's University found evidence that higher rates of interpersonal stress generation (in a sample of adolescent girls with a history of childhood maltreatment) predicted depression (Holshausen, Bowie, & Harkness, 2016; Harkness, Lumley, & Truss, 2008). Research done at the University of Toronto addressed whether people act in ways that keep existing stress going (i.e., stress continuation) or generate new stress. The data suggested that not only was new stress created, but stress generation was implicated in both depression and anxiety (Uliaszek et al., 2012).

Today's leading explanations for major depressive disorder point to neuroscience, psychological, or socio-cultural factors. Many theorists believe that the various explanations should be combined to more fully understand people with this disorder (Beck & Bredemeier, 2016). We will examine them separately here so that each perspective is clear.

15.2 Psychology Around Us

The Case of Andrea Yates

On the morning of June 20, 2001, 36-year-old Andrea Yates called police and explained that she had drowned her five children in the bathtub because "they weren't

developing correctly." She recounted the order in which the children had died: first 3-year-old Paul, then 2-year-old Luke, followed by 5-year-old John, 6-month-old Mary, and 7-year-old Noah.

As many as 80 percent of mothers experience "baby blues" soon after giving birth, and around 17 percent display the clinical syndrome of *postpartum depression* (Shorey et al., 2018). Postpartum psychosis, by contrast, is an entirely different disorder (VanderKruik et al., 2017; Bergink, Rasgon, & Wisner, 2016).

Postpartum psychosis affects about 1 to 2 of every 1,000 mothers who have recently given birth (VanderKruik et al., 2017). The symptoms apparently are triggered by the enormous shift in hormone levels that occur after delivery (Bergink et al., 2016). Within days or at most a few months of childbirth, the woman develops signs of losing touch with reality, such as delusions (for example, she may become convinced that her baby is the devil); hallucinations (perhaps hearing voices); extreme anxiety, confusion, and disorientation; disturbed sleep; and illogical or chaotic thoughts (for example, thoughts about killing herself or her child).

Women with a history of bipolar disorder, schizophrenia, or major depressive disorder are particularly vulnerable to the disorder (Raza & Raza, 2019). In addition, women who have previously experienced postpartum depression or postpartum psychosis have an increased likelihood of developing this disorder after subsequent births (Raza & Raza, 2019; Nonacs, 2007). Andrea Yates, for example, had developed signs of postpartum depression (and perhaps postpartum psychosis) and attempted suicide after the birth of her fourth child. At that time, however, she appeared to respond well to a combination of medications, and so she and her husband later decided to conceive a fifth child (King, 2002).

After the birth of her fifth child, the symptoms did in fact recur, along with features of psychosis. Yates again attempted suicide. Although she was hospitalized twice and treated with various medications, her condition failed to improve. Six months after giving birth to Mary, her fifth child, she drowned all five of her children.

Most clinicians who are knowledgeable about this rare disorder agree that Yates was indeed a victim of postpartum psychosis. Although only a fraction of women with the disorder actually harm their children (estimates run as high as 4 percent), the Yates case reminds us that such an outcome is indeed possible (VanderKruik et al., 2017; Raza & Raza, 2019). The case also reminds us that early detection and treatment are critical (Bergink et al., 2016).

After a second trial for murder in 2007, Yates was found *not guilty by reason of insanity* and sent to a high-security mental health facility for treatment. Some months later, she was transferred to a low-security state mental hospital where she continues to receive treatment.

How Do Neuroscientists Explain Depression?

If people inherit a predisposition to major depressive disorder, we would expect a particularly large number of cases among the close relatives of depressed persons (Neale,

2013). Twin studies support this expectation (Wang et al., 2020; Waszczuk et al., 2016). One investigation, for example, looked at nearly 200 pairs of twins. When a *monozygotic* (*identical*) twin had depression, there was a 46 percent chance that the other twin would have the same disorder. In contrast, when a *dizygotic* (*fraternal*) twin had depression, the other twin had only a 20 percent chance of developing the disorder (McGuffin et al., 1996).

If genetic influences are indeed at work in unipolar depression, what biological factors might ultimately produce the disorder? Researchers have focused most often on abnormal neurotransmitter activity—namely, low activity of norepinephrine and serotonin (Ferrari & Villa, 2017).

In the 1950s, several pieces of evidence began to point to these neurotransmitters. First, medical researchers discovered that several medications for high blood pressure often caused depression (Ayd, 1956). As it turned out, some of these medications lowered norepinephrine activity and others lowered serotonin. A second piece of evidence was the discovery of the first truly effective antidepressant drugs. These drugs were discovered almost by accident. In 1956, Roland Kuhn, a psychiatrist working in Switzerland, was administering a new trial drug to patients with schizophrenia. The drug did not seem to work, and in fact made symptoms worse in some patients. Kuhn noticed, however, that those patients with comorbid symptoms of depression showed improvement in their depressive symptoms while on the drug. Kuhn tried the drug with patients who were only showing depressive symptoms, and many of them improved dramatically (Cahn, 2006). With these initial observations in hand, researchers soon learned that they could relieve the symptoms of depression for some people by increasing either norepinephrine or serotonin activity (Bunney & Davis, 1965; Schildkraut, 1965).

An enormous number of studies over the past half-century have further supported the notion that major depressive disorder is related to low activity of norepinephrine and/or serotonin. Neuroscience research has also indicated that the body's endocrine system may play a role in depression. People with depression have been found to have high levels of cortisol, the hormone released by the adrenal glands during times of stress (Keller et al., 2017; Palazidou, 2012). This relationship is not all that surprising, given that stressful events often seem to trigger depression. Recent research suggests that cortisol levels may, in fact, predict responsiveness to therapy for depressive symptoms (Fischer et al., 2016).

How Do Cognitive-Behavioural Theorists Explain Depression?

Cognitive-behavioural theorists believe that people with severe depression acquire distinctly negative behaviours and think in dysfunctional ways that help cause and sustain their disordered symptoms (Kazantzis et al., 2018; Cristea et al., 2015). The two most influential cognitive-behavioural explanations centre on the phenomenon of learned helplessness and on the power of negative thinking.

Learned Helplessness

Since the mid-1960s, psychologist Martin Seligman has been developing the *learned helplessness* theory of depression (Maier & Seligman, 2016; Forgeard et al., 2011; Gillham et al., 2011; Seligman 1992, 1975). This theory holds that people become depressed when they think: (1) that they no longer have control over the rewards and punishments in their

lives, and (2) that they themselves are responsible for this helpless state.

Seligman's theory first began to take shape when he was working with laboratory dogs. He found that when dogs were given inescapable shocks, they came to learn that they have no control over the unpleasant punishments (shocks) in their lives. That is, they learned that they were helpless to do anything to change negative situations. You may recall from Chapter 7 that this phenomenon is called *learned helplessness*. Moreover, when later placed in a new situation where they could in fact escape shocks and control their fate, the dogs continued to act as if they were generally helpless. They would just lie in their experimental boxes and accept the shocks. Seligman noted that the effects of learned helplessness greatly resemble the symptoms of human depression, and he proposed that people become depressed after developing a general belief that they have no control over the rewards and punishments in their lives (Maier & Seligman, 2016; Seligman, 1975).

The learned helplessness explanation of depression has been revised somewhat over the past two decades. According to another version of the theory, the *attribution-helplessness theory*, when people view events to be beyond their control, they ask themselves why this is so (Abramson et al., 2002, 1989, 1978). If they attribute their present lack of control to some *internal* cause (some deficiency in themselves) that is both *global* (a deficiency that is wide-ranging) and *stable* (a deficiency that will continue for a long time), they may well feel helpless to prevent future negative outcomes and they may experience depression. If they make other kinds of attributions, this depressed reaction is unlikely.

Image Source/Getty Images

Breaking up is hard to do **Having your significant other break up with you can be devastating. According to the attribution-helplessness theory, if a person attributes the breakup to their own internal shortcomings rather than to more specific events, the breakup could cause depression.**

Consider a university student whose girlfriend breaks up with him. If he attributes this loss of control to an internal cause that is both global and stable—"It's my fault [internal]; I ruin everything I touch [global], and I always will [stable]"—he then has reason to expect loss of control in the future and may generally experience a sense of helplessness. According to the attribution-helplessness view, he is a prime candidate for depression. If the student instead

attributes the breakup to causes that are more specific ("The way I've behaved the past couple of weeks blew this relationship"), unstable ("I don't usually act like that"), or external ("She never did know what she wanted"), he might not expect to lose control again and would probably not experience helplessness and depression (see photo).

Negative Thinking

Like Seligman, Aaron Beck believes that negative thinking plays a key role in depression. Beck, however, points to *dysfunctional attitudes*, *errors in thinking*, the *cognitive triad*, and *automatic thoughts* as the keys to the clinical syndrome (Beck & Bredemeier 2016; Beck & Haigh, 2014; Beck & Weishaar, 2011; Beck, 2002, 1991, 1967).

Beck believes that some people develop *dysfunctional attitudes*, such as "My general worth is tied to every task I perform," and "If I fail, others will feel repelled by me." In addition, Beck believes that those same people often commit errors in their thinking, such as arbitrary inferences or magnification.

According to Beck, this steady onslaught of dysfunctional attitudes and illogical thinking eventually triggers extended rounds of negative thinking in these individuals. The thinking typically takes three forms and is therefore termed the **cognitive triad**: the individuals repeatedly interpret: (1) *their experiences*, (2) *themselves*, and (3) *their futures* in negative ways that lead them to feel depressed. That is, depressed people interpret their experiences as burdens that repeatedly defeat or deprive them. They view themselves as undesirable, worthless, and inadequate. And they regularly see the future as bleak, as seen in **Figure 15.2**.

> **cognitive triad** a pattern of thinking in which individuals repeatedly interpret their experiences, themselves, and their futures in negative ways that lead them to feel depressed.

Finally, depressed people experience **automatic thoughts**, a steady train of unpleasant thoughts that keep suggesting to them that they are inadequate and that their situation is hopeless. Beck labels these thoughts "automatic" because they seem to just happen, as if by reflex. In the course of only a few hours, depressed people may be visited by hundreds of such thoughts: "I'm worthless. . . . I let everyone down. . . . Everyone hates me. . . . My responsibilities are overwhelming. . . . I've failed as a parent. . . . I'm stupid. . . . Everything is difficult for me. . . . Things will never change."

> **automatic thoughts** specific upsetting thoughts that arise unbidden.

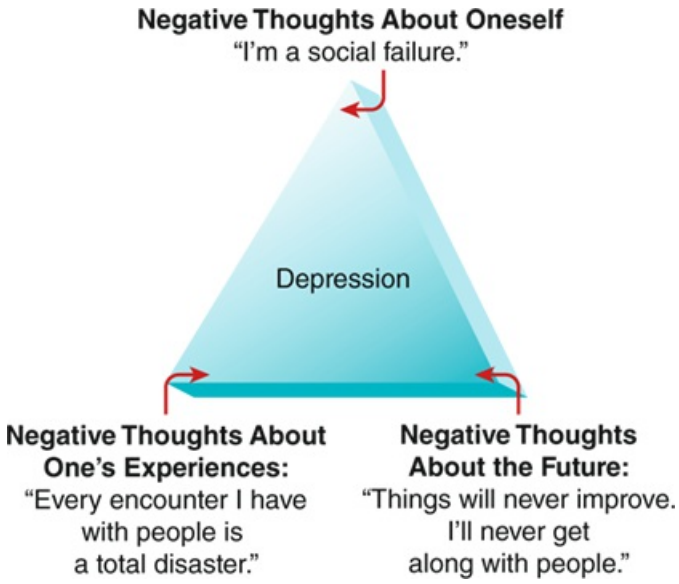

FIGURE 15.2 Cognitive triad of depression **According to Aaron Beck, a regular pattern of these three types of negative thoughts increases vulnerability to depression.**

While it is not entirely clear whether this sort of negative thinking is a cause or a symptom of depression, Beck's explanation has received considerable research support. Several studies confirm, for example, that depressed people hold dysfunctional attitudes, and the more dysfunctional attitudes they hold, the more depressed they tend to be (Qin et al., 2020). Other research supports the theory of a cognitive triad in depressed individuals. For example, studies indicate that depressed participants recall unpleasant experiences more readily than positive ones, rate themselves lower than non-depressed subjects do, and select pessimistic statements in storytelling tests (for example, "I expect my plans will fail") (Bianchi et al., 2018).

More recent research has identified an early framework for the neurobiological underpinnings for Beck's cognitive theory (Beck & Bredemeier, 2016; Belzung, Willner, & Philippot, 2015). This research suggests bottom-up activation from subcortical structures involved in emotional control that are unchecked by top-down cognitive processes from the frontal cortex. In other words, a heightened emotional response cannot be regulated. Research that integrates knowledge across various levels of analysis is helping to move the field not only toward a better understanding of etiology, but also toward a better understanding of treatment options.

How Do Socio-Cultural Theorists Explain Depression?

Socio-cultural theorists propose that social forces play an important role in the development of major depressive disorder. Their belief is supported by the finding, discussed earlier, that depression is often triggered by outside stressors. In addition, the unavailability of social support seems to play a significant role in the onset of depression. People who are separated or divorced display three times the depression rate of married or widowed persons, and double the rate of people who have never been married (Brown & Harris, 2012; Assari, 2017; Neitzke, 2016; Brown, 2010). A poignant example of the

potential impact of social forces are the experiences of Indigenous Canadians with residential schools. The individual and transgenerational traumas associated with residential school experiences are associated with many issues including higher rates of suicidal ideation (see Indigenous Experiences 15.1).

15.1 Indigenous Experiences

Suicide Ideation and Attempts and Residential School Familial History

Antonette White recalls a suicide at her Kuper Island residential school in Chemainus, British Columbia. All students were forced to come in and look at the deceased victim. "I remember the one young fellow that hung himself in the gym, and they brought us in there, and showed, showed us, as kids, and they just left him hanging there, and, like, what was that supposed to teach us? You know I'm 55 years old, and I still remember that" (White, 2012, p. 117).

Suicidal behaviour includes suicide ideation (recurrent ideas and thoughts of ending one's life), suicide attempts (an event where one tries to kill one's self), and completed or fatal suicide (where death occurs). Suicide ideation predicts suicide attempts, and suicide attempts predict suicide completions. Suicide behaviour is an indicator of extreme psychological distress, involving intense feelings of hopelessness, anxiety, and depression, and is often accompanied by self-destructive behaviours (McQuaid et al., 2017).

Completed suicide rates are twice as high among Indigenous peoples as they are in non-Indigenous peoples, for all age groups. First Nations people, both on and off reserve, as well as Metis and Inuit people, die by suicide at higher rates than non-Indigenous people. It is, however, important to note that national suicide rates do not necessarily reflect individual communities. For example, in small Indigenous communities, the impact of suicide is often more significant and widespread since many individuals are related and thereby share many adverse environments and experiences. Conversely, other regions or communities may have very low rates of suicide (Kumar & Tjepkema, 2019; Chandler et al., 2003). Nevertheless, there is increasing evidence to support the idea that the high rates of suicide among Indigenous peoples today originated with exposures to historical and intergenerational inequities and unresolved traumas related to colonization and continue due to ongoing injustice and marginalization (Bombay et al., 2014). In particular, outcomes associated with direct or indirect (i.e., intergenerational) residential school experience elevate risk for physical and mental problems (Elias et al., 2012).

Robyn McQuaid, at Carleton University, and colleagues (2017) studied the impact of intergenerational residential school attendance and its relationship to present-day suicide ideation and attempts. Participants identified whether a parent or a grandparent, or both, had attended a residential school (i.e., one or two previous generations). Individuals who attended residential schools themselves were excluded from analyses. The results of the study indicated that: (1) a familial history of

residential school attendance was associated with a significantly higher risk of suicide ideation and attempts compared with Indigenous people without a residential school history; (2) the results for one or two generations of familial involvement did differentially affect suicide behaviours; and (3) familial transmission of suicidal behaviour cannot be completely explained by psychiatric disorders or current levels of distress.

THE CANADIAN PRESS/Justin Tang

Hopeful messages in Inuktitut and English Students from the Nunavut Sivuniksavut attend an annual suicide prevention event in Ottawa. Hosted by the National Inuit Youth Council and Inuit Tapiriit Kanatami, students send messages to celebrate life and to raise awareness about suicide prevention.

It has been suggested that cultural continuity may play an important protective role in suicide prevention for Indigenous people (Chandler and Lalonde, 2019; Mehl-Madrona, 2016). "[Many] First Nations peoples have maintained their cultural knowledge and ways of living in relation to the land and each other, which is grounded in and contributes to their extreme strength, resilience, and capacity for healing and renewal" (McQuaid et al., 2017, p. 428).

Critical Thinking Questions

Why is it important to be sure not to overgeneralize statements regarding suicide rates among Indigenous groups or populations?

How are residential school experiences linked to present-day suicidal ideation and attempts among Indigenous people?

What is cultural continuity and what roles does it potentially play in matters of Indigenous suicide?

Individuals whose lives are isolated and without intimacy are particularly prone to becoming depressed during times of stress (Domènech-Abella, Mundó, Haro, & Rubio-Valera, 2019; Brown, 2010; Kendler, Myers, & Prescott, 2005). Studies conducted in England several decades ago showed that women who had three or more young children,

lacked a close confidante, and had no outside employment were more likely than other women to become depressed after experiencing stressful life events (Brown, 2010; Brown et al., 2005). Studies have also found that depressed people who lack social support remain depressed longer than those who have a supportive spouse or warm friendships (Van Den Brink et al., 2018). These sorts of research findings have contributed to the development of social prescribing in Britain where doctors, with the support of community liaison workers, prescribe social expediences such as gardening or reading clubs to some of their lonely isolated senior patients (Chatterjee, Camic, Lockyer, & Thomson, 2018).

Bipolar Disorder

People with a *bipolar disorder* often describe their lives as an emotional roller coaster. They shift back and forth between extreme moods, experiencing both the lows of depression and the highs of mania. Unlike people sunk in the gloom of depression, those in a state of *mania* experience dramatic and inappropriate elevation in mood. The symptoms of mania span the same areas of functioning—emotional, motivational, behavioural, cognitive, and physical—as those of depression, but mania affects these areas in an opposite way.

Jonathan Hayward/The Canadian Press

Bipolar disorder Margaret Trudeau, ex-wife of former prime minister Pierre Trudeau and mother of current Prime Minister Justin Trudeau, has spoken openly about her struggle with bipolar disorder and has written a book about her experiences called *Changing My Mind*. She is a fierce advocate for mental health in Canada and is engaged in fighting the stigma of mental illness.

In mania, people have active, powerful emotions in search of an outlet. Their mood of euphoric joy or extreme agitation is out of all proportion to the actual events in the

person's life. In the motivational realm, people with mania want constant excitement, involvement, and companionship. Correspondingly, they move quickly and talk rapidly and loudly. In the cognitive realm, individuals with mania usually show poor judgment and planning. Filled with optimism, they rarely listen when others try to slow them down, interrupt their buying sprees, or prevent them from investing money unwisely. They often hold an inflated opinion of themselves, and sometimes their self-esteem approaches grandiosity (for example, an exaggerated belief in their personal importance). Finally, in the physical realm, the individuals feel remarkably energetic. They typically get little sleep, yet feel and act wide awake (Anderson, Haddad, & Scott, 2012).

Surveys from around the world indicate that between 1 and 2.6 percent of all adults suffer from a bipolar disorder at any given time (Ferrari et al., 2016; Grunze, 2015). According to the Canadian Mental Health Association (2014b), 1 percent of Canadians suffer from bipolar disorder (see photo). Nonetheless, bipolar is considered to be one of the most debilitating disorders globally (Magalhaes et al., 2012). According to most studies, bipolar disorders are equally common in women and men and among all socio-economic classes and ethnic groups (Anderson et al., 2012).

Throughout the first half of the twentieth century, the search for the causes of bipolar disorders made little progress. More recently, neuroscience research has produced some promising clues. There is now strong evidence that a combination of gene abnormalities plays a major role in the development of bipolar disorders (Andreassen & Tesli, 2016; Scaini et al., 2020; Grieco & Edwards, 2010; Schulze & McMahon, 2009). Familial, twin, and adoption studies indicate that bipolar disorder is highly heritable (heritability range: 0.85–0.89) (McGuffin et al., 2003). There is also evidence that bipolar disorder may be linked to ion dysregulation and reduced sodium pump activity (Mack et al., 2019; Alda, 2015).

The diathesis-stress model may partially account for the development of bipolar disorder. Although genes and biological factors appear to play key roles, there is growing evidence that stress and certain kinds of environmental events also must occur in order for episodes of bipolar disorder to unfold. Some studies suggest, for example, that major stress must combine with an individual's genetic predisposition for episodes of bipolar disorder to occur, particularly in early episodes (Lex, Bäzner, & Meyer, 2017; Brietzke et al., 2012). Still other studies suggest that certain kinds of positive events (ones involving the attainment of or striving toward goals) are needed for bipolar disorders to unfold in biologically predisposed people. The idea is that individuals predisposed to develop bipolar disorder overreact to the arousal produced by goal-related events and develop the mania-related symptoms of bipolar disorder (Alloy et al., 2011; Bender & Alloy, 2011).

Anxiety Disorders

LEARNING OBJECTIVE 4

Describe the various types of anxiety disorders, and explain some causes of these disorders.

Read through the following example of a conversation between a patient named Bob and his doctor, paying particular attention to what Bob says about his feeling of anxiety.

Bob: It's been an awful month. I can't seem to do anything. I don't know whether I'm coming or going. I'm afraid I'm going crazy or something.

Doctor: What makes you think that?

Bob: I can't concentrate. My boss tells me to do something and I start to do it, but before I've taken five steps I don't know what I started out to do. I get dizzy and I can feel my heart beating and everything looks like it's shimmering or far away from me or something—it's unbelievable.

Doctor: What thoughts come to mind when you're feeling like this?

Bob: I just think, "Oh, Christ, my heart is really beating, my head is swimming, my ears are ringing—I'm either going to die or go crazy."

Doctor: What happens then?

Bob: Well, it doesn't last more than a few seconds, I mean that intense feeling. I come back down to earth, but then I'm worrying what's the matter with me all the time, or checking my pulse to see how fast it's going, or feeling my palms to see if they're sweating.

Doctor: Can others see what you're going through?

Bob: You know, I doubt it. I hide it. I haven't been seeing my friends. You know, they say "Let's stop for a beer" or something after work and I give them some excuse—you know, like I have to do something around the house or with my car. I'm not with them when I'm with them anyway—I'm just sitting there worrying. My friend Pat said I was frowning all the time. So, anyway, I just go home and turn on the TV or pick up the sports page, but I can't really get into that either.

Some people suffer such disabling levels of fear and anxiety that they cannot lead a normal life (see photo). Their discomfort is too severe or too frequent; it lasts too long; or it is triggered too easily. These people are said to have an *anxiety disorder*. Anxiety disorders are collectively the most common mental disorders in Canada. In any given year, about 12 percent of the adult population suffers from one or another of the anxiety disorders identified by DSM-5 (Ruscio et al., 2017; Louise, O'Donnell Siobhan, & Jean, 2017; O'Donnell et al., 2016; Kessler et al., 2012).

Stockbyte/Getty Images

Feeling anxious **Anxiety is a normal part of life—everyone feels anxious sometimes. Anxiety becomes a problem when it interferes with a person's ability to participate fully in society.**

There are several kinds of anxiety disorders. Individuals with *generalized anxiety disorder* experience persistent feelings of worry and anxiety. People with *social anxiety disorder* display persistent fears of social or performance situations. People with *phobias* have a persistent and irrational fear of a specific object, activity, or situation. Individuals with *panic disorder* have recurrent attacks of terror. Those with *obsessive-compulsive disorder* feel overrun by recurrent thoughts that cause anxiety or by the need to perform repetitive actions to reduce anxiety. And those with *posttraumatic stress disorder (PTSD)* are tormented by overwhelming intrusive fears about the horrors associated with the traumatizing event—even when the event is long over and they are otherwise safe and well.

Most individuals with one anxiety disorder suffer from a second one as well (Goldstein-Piekarski, Williams, & Humphreys, 2016; Miloyan et al., 2016). In the above example, Bob experiences the excessive worry found in generalized anxiety disorder, as well as the repeated attacks of terror that mark panic disorder.

Generalized Anxiety Disorder

People with **generalized anxiety disorder (GAD)** experience excessive anxiety accompanied by at least three of the following symptoms: restlessness, keyed-up behaviour, fatigue, difficulty concentrating, muscle tension, and sleep problems. These symptoms vary widely from one person to another (see **Figure 15.3**). The incessant worrying causes self-doubt, and the simplest decision represents a risky outcome; for example, worrying about whether to make spaghetti or veggie burgers for dinner.

generalized anxiety disorder (GAD) an anxiety disorder in which people feel excessive anxiety and worry under most circumstances.

Surveys suggest that as many as 4 percent of the North American population have symptoms of GAD in any given year (Ruscio et al., 2017; Bandelow & Michaelis, 2015; Haller et al., 2014). Women diagnosed with the disorder outnumber men by 2 to 1. The leading explanations of generalized anxiety disorder come from the cognitive and neuroscience models.

How Do Cognitive Theorists Explain Generalized Anxiety Disorder?

As with depression, cognitive theorists suggest that generalized anxiety disorder is caused in part by *dysfunctional assumptions*. Aaron Beck argues that people with GAD constantly hold silent assumptions that imply they are in imminent danger—for example, "A situation or a person is unsafe until proven to be safe" or "It is always best to assume the worst" (Beck & Weishaar, 2011; Beck, Emery, & Greenberg, 1985). Similarly, Albert Ellis (2011, 2002, 1962) claimed that people who are generally anxious hold the following "irrational" assumptions in particular:

> "It is a dire necessity for an adult human being to be loved or approved of by virtually every significant other person in his community."
>
> "It is awful and catastrophic when things are not the way one would very much like them to be."
>
> "If something is or may be dangerous or fearsome, one should be terribly concerned about it and should keep dwelling on the possibility of its occurring."
>
> "One should be thoroughly competent, adequate, and achieving in all possible respects if one is to consider oneself worthwhile."
>
> (Ellis, 1962)

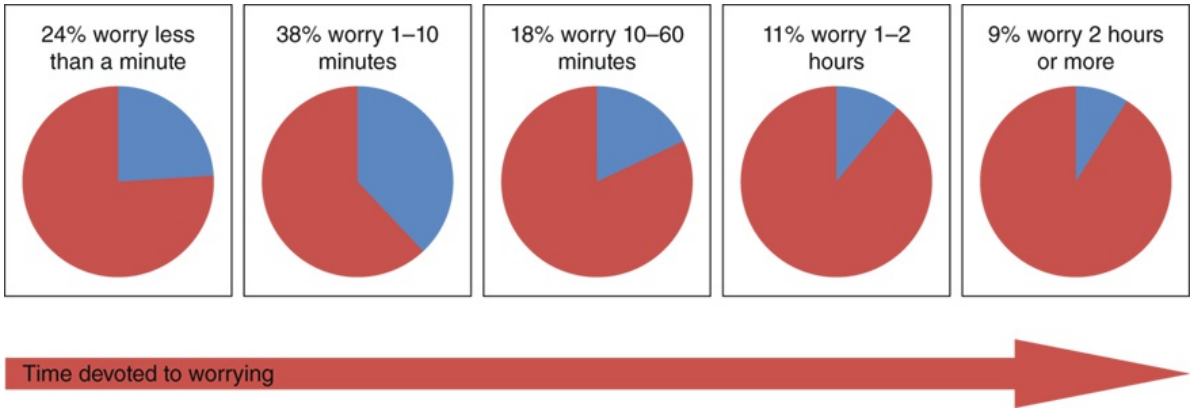

FIGURE 15.3 Some people worry more than others In one survey, 24 percent of post-secondary students said they spend less than 1 minute at a time worrying about something. In contrast, 9 percent worry for more than 2 hours.

Source: Adapted from Tallis, F., Davey, G., & Capuzzo, N. (1994). The phenomenology of non-pathological worry: A preliminary investigation. In G. Davey & F. Tallis (Eds.), *Worrying: Perspectives on theory, assessment and treatment* (pp. 61–89). Chichester, UK: John Wiley & Sons.

In recent years, some additional cognitive explanations for GAD have emerged. Sometimes

called *new wave (or third wave) cognitive explanations*, each of these explanations builds on the notions of Ellis and Beck and their emphasis on perceived danger (DeRubeis, Keefe, & Beck, 2019; Dimidjian et al., 2016; Ritter et al., 2010). According to one such explanation, the *intolerance of uncertainty theory*, certain individuals consider it unacceptable that negative events may occur, even if the possibility of occurrence is very small. Given that life is filled with uncertain events, such individuals may come up against several "unacceptable" events each day. Worrying constantly that unacceptable events are on the verge of happening, the individuals are particularly vulnerable to the development of generalized anxiety disorder (Shihata, McEvoy, Mullan, & Carleton, 2016).

According to this theory, people with GAD keep worrying in an effort to find "correct" solutions to situations at hand, expecting that correct solutions will restore certainty to the situations. However, because they can never really be sure that a given solution is a correct one, they are always left to grapple with intolerable levels of uncertainty, triggering new rounds of worrying and new efforts to find correct solutions. The large jumps in uncertainty for everyone associated with the COVID-19 pandemic definitely complicated things for those intolerant of uncertainty and likely, at least temporarily we hope, tested many more people's tolerance of uncertainty (Koffman, Gross, Etkind, & Selman, 2020).

In support of this theory, studies have found that people with GAD display greater levels of intolerance of uncertainty than people with normal degrees of anxiety (Bottesi et al., 2016; Daitch, 2011; Ouellet, Langlois, Provencher, & Gosselin, 2019; Wright, Lebell, & Carleton, 2016). At the same time, however, recent research indicates that people with other kinds of anxiety disorders may also display high levels of intolerance of uncertainty (Nelson, Hodges, Hajcak, & Shankman, 2015).

How Do Neuroscientists Explain Generalized Anxiety Disorder?

One biological explanation of generalized anxiety disorder focuses on neurotransmitter imbalances. In normal fear reactions, key neurons throughout the brain fire more rapidly, triggering the firing of still more neurons and creating a general state of excitability throughout the brain and body. This state is experienced as fear or anxiety. After neuron firing continues for a while, it apparently triggers a *feedback system*—that is, brain and body activities that reduce the level of excitability. Some neurons throughout the brain release the neurotransmitter *gamma-aminobutyric acid (GABA)*, which then binds to GABA receptors on certain neurons. GABA carries inhibitory messages. That is, when GABA is received at a neuron's receptor, it instructs those neurons to stop firing. The state of excitability is thereby halted, and the experience of fear or anxiety subsides (Rudolph & Moss, 2019).

Some neuroscientists now believe that a malfunction in this feedback system may cause fear or anxiety to go unchecked (Tovote, Fadok, & Lüthi, 2015; Bremner & Charney, 2010). In fact, when some investigators have reduced GABA's ability to bind to GABA receptors, they have found that animal subjects react with heightened anxiety (Skórzewska et al., 2014). This finding suggests that people with generalized anxiety disorder may have ongoing problems in their anxiety feedback system. Perhaps they have too few GABA receptors, or their GABA receptors do not properly capture the neurotransmitter (Li et al., 2016). Benzodiazepines—a class of drugs that reduce anxiety (and will be discussed in greater detail in Chapter 16)—exert their effect by stimulating GABA.

Recent research further clarifies that the root of generalized anxiety disorder is probably more complicated than GABA alone. Other neurotransmitters, such as acetylcholine and serotonin, may also play important roles in GAD as well (Tafet & Nemeroff, 2020; Martin & Nemeroff, 2010). Moreover, emotional reactions of various kinds are tied to brain *circuits*—networks of brain structures that work together, triggering each other into action with the help of neurotransmitters and producing particular kinds of emotional reactions. It turns out that the circuit that produces anxiety reactions includes the *prefrontal cortex*, *anterior cingulate*, and *amygdala*. According to several studies, this circuit may function improperly in people with GAD (Robinson, Pike, Cornwell, & Grillon, 2019; Schienle, Ebner, & Schafer, 2011).

Social Anxiety Disorder

Many people worry about interacting with others or talking or performing in front of others. A number of entertainers, from singer Barbra Streisand to actor Anthony Hopkins, have described major bouts of anxiety before performing. Social fears of this kind are unpleasant and inconvenient, but usually the people who have them manage to function adequately, some at a very high level.

Image Source/Getty Images

Public performances **Most people do not enjoy standing up and presenting in front of a class or group of people. People with social anxiety disorder have particularly intense and irrational fears of not only talking or performing in front of others, but even of just being in regular social situations.**

People with a **social anxiety disorder**, by contrast, have severe, persistent, and irrational fears of social or performance situations in which embarrassment may occur (see photo). The social anxiety may be *narrow*, such as a fear of talking in public or writing in front of others, or it may be *broad*, such as a general fear of functioning poorly in front of others. In both forms, people repeatedly judge themselves as performing less adequately than they actually do.

social anxiety disorder an anxiety disorder in which people feel severe, persistent, and irrational fears of social or performance situations in which embarrassment may occur.

A social phobia can interfere greatly with one's life (Wersebe et al., 2018; Peschard & Philippot, 2016). A person who is unable to interact with others or speak in public may fail to perform important responsibilities. One who cannot eat in public may reject dinner invitations or other social opportunities. Since most people with this phobia keep their fears secret, their social reluctance is often misinterpreted as snobbery, lack of interest, or hostility.

Surveys indicate that at least 7.1 percent of people in Western countries—around three women for every two men—experience social anxiety disorder in any given year. Around 12 percent develop this problem at some point in their lives (Ohayon & Schatzberg 2010; Alfano & Beidel, 2011). It often begins in late childhood or adolescence, and may continue into adulthood. Research finds that people living in poverty are 50 percent more likely than wealthier people to display a social phobia (Bosma, Simons, & Groffen, 2016; Sareen et al., 2011). Moreover, in several studies, minority group participants scored higher than non-minority group participants on surveys of social anxiety (Bandelow & Michaelis, 2015; Goetter et al., 2020).

Lynn Alden and her colleagues at the University of British Columbia explain social anxiety as failure to meet self-determined extreme perfectionistic standards, while simultaneously viewing one's self-efficacy as too low to achieve identified standards in order to meet these high expectations (Alden, Ryder, & Mellings, 2002; Glazier & Alden, 2017). Similarly, Paul Hewitt from the University of British Columbia and Gordon Flett from York University and their colleagues report that socially anxious people tend to be high in perfectionistic self-presentation and cannot allow themselves to make any errors in public (Nepon, Flett, & Hewitt, 2016; Flett & Hewitt, 2014; Hewitt et al., 2003).

The most influential explanations for social anxiety disorder have come from cognitive-behavioural theorists (Benbow & Anderson, 2019; Hofmann & Otto, 2017; Gregory & Peters, 2016). They hold that, like people with generalized anxiety disorder, individuals with this disorder have dysfunctional cognitions that help produce and maintain their symptoms. In the case of social anxiety disorder, those cognitions all centre on the social arena. According to the cognitive-behavioural explanations, people with this disorder hold a cluster of social beliefs and expectations that work against them. These include the following (Gregory, Wong, Marker, & Peters, 2018; Wong et al., 2017; Nordahl & Wells, 2017; Hope et al., 2010):

> They hold unrealistically high social standards and so believe that they must perform perfectly in social situations. Given such standards, they cannot develop social goals that are reasonable and achievable.
>
> They view themselves as unattractive social objects.
>
> They view themselves as socially unskilled and inadequate.
>
> They believe that they are in danger of behaving incompetently in social situations.
>
> They believe that clumsy or inept behaviours in social situations will always lead to terrible consequences.
>
> They believe that they have no control over feelings of anxiety that emerge during social situations.

Cognitive-behavioural theorists contend that, as a result of this cluster of dysfunctional notions, individuals with social anxiety disorder anticipate that social disasters will occur, and so repeatedly perform "avoidance" and "safety" behaviours to help prevent or minimize such disasters (Hofmann & Otto, 2017). Avoidance behaviours include, for example, talking only to familiar persons at meetings or parties. Safety behaviours include holding on to a podium during a classroom presentation so that their hands don't tremble, or wearing makeup to cover blushing. Finally, after a social event has occurred, the individuals keep going over the details of the events in their mind. They overestimate how badly things went and what negative repercussions may unfold. These ruminations serve to keep the events alive, and also feed into the individuals' fears about future social situations (Topper et al., 2017; Hope et al., 2010).

Why do some individuals, and not others, have such dysfunctional cognitions? Researchers have identified a number of factors. These include genetic predispositions, trait tendencies, biological abnormalities, traumatic childhood experiences, and past parent–child interactions (Dias et al., 2016; Brozovich & Heimberg, 2011; Kuo et al., 2011). (See Practically Speaking 15.1.)

15.1 Practically Speaking

Anxious? Take Steps!

Even before the added stresses and uncertainties caused by the COVID-19 pandemic, emerging adults (18- to 28-year-olds) have been experiencing anxiety lately. A survey of over 55,000 Canadian college and university students conducted in the spring of 2019, a year before the pandemic, found that 88 percent of respondents said that in the previous 12 months, they had felt overwhelmed by "all they have to do" at some point and that 69 percent (54 percent of males and 75 percent of females) had "felt overwhelming anxiety" at times (American College Health Association, 2019). These percentages are up significantly compared with similar surveys conducted 5 to 10 years previously (Twenge, 2017; Twenge, Joiner, Rogers, & Martin, 2018). When others describe emerging adults with terms like "sheltered," "coddled," or "fragile," or use nasty names like "snowflake," it is inappropriate and unfair because they ignore the much higher levels of stress and uncertainty in the social and economic world that emerging adults are facing today (Levine, 2020).

This data indicates that the odds are high that you have been challenged by anxiety recently. How are you doing? Have you received any help or support in figuring out how to manage anxiety? Have you tried to help a friend with anxiety issues? Do you know where you can go and what support services or programs you or your friends can connect with that will help with anxiety issues? Here are some things you can do to find out about and connect with some of the many readily available resources that can help you or your friends with anxiety challenges.

> Your college or university will have a number of in-person and online programs and services focused on mental health and wellness, including resources specifically on anxiety. On your college or university's website, use search terms like "wellness," "mental health," "stress," "anxiety," or "resilience," and you should

find several resources that can help with anxiety.

One of the things that most often gets in the way of seeking help is the belief that the anxiety you feel is somehow your fault. Talking to someone about how you feel can help. Alternatively, a good place to start is by answering a few questions about how things have been going for you recently. You can do this online and it can help you decide if you need to talk with someone. A group in British Columbia called HereToHelp, in collaboration with Anxiety Canada, has a confidential online screening tool that can help you gain some clarity and it will provide some suggestions of contacts and possible actions that can help. <www.heretohelp.bc.ca>.

Every province has a number you can call just to talk with someone about how you are feeling but also to find out about programs, supports, and resources in your area. Crisis Services Canada can help you find links to services in your area: <www.crisisservicescanada.ca>.

Find and use the resources and supports that are available to you—they will really help!

Phobias

As you saw in Chapter 7, a **phobia** (from the Greek for "fear") is a persistent and unreasonable fear of a particular object, activity, or situation. Most phobias fall under the category *specific phobia*, an intense fear of a specific object or situation. See the list of the 10 most common phobias in **Table 15.5**. There are five categories of specific phobia: (1) animals (dogs, cats, snakes, spiders); (2) natural environments (heights, dark, thunder); (3) situations (enclosed spaces, bridges) (see photo); (4) blood and injections; and (5) other (choking, vomiting, loud noises, clowns). People can form a phobia to almost anything (red hair or bald men), but some phobias are more common than others. Surveys suggest that 7.7 percent of people in Canada suffer from at least one specific phobia in any given year (O'Donnell et al., 2016; Kessler et al., 2010).

phobia a persistent and unreasonable fear of a particular object, activity, or situation.

blickwinkel/Alamy Stock Photo

Claustrophobia A fear of enclosed spaces such as elevators is one of the most common phobias.

Behavioural principles provide the leading explanations for specific phobias (Eaton, Bienvenu, & Miloyan, 2018; Gamble, Harvey, & Rapee, 2010). According to behaviourists, *classical conditioning* is one way of acquiring fear reactions to objects or situations that are not really dangerous. Let's say, for example, that a frightening event, such as a lightning strike (*unconditioned stimulus*) naturally elicits a reaction of fear (*unconditioned response*) in an individual. In such a situation, it is possible that a harmless object, such as raindrops (*conditioned stimulus*)—an object that had simply accompanied the frightening event—will come to also elicit a fear reaction (*conditioned response*) in the person. A dated but useful learning theory of phobias is Mowrer's (1950) two-factor theory of phobia learning, which suggests that the fears associated with phobic objects are learned through classical conditioning, while the avoidance behaviours associated with phobias are reinforced through operant conditioning. So, for example, a person might develop a social phobia as a result of a panic attack in a crowd (classical conditioning), and then stop going out to avoid crowds (operant conditioning).

According to behaviourists, another way of acquiring a fear reaction is through *modelling*—that is, through observation and imitation (Bandura & Rosenthal, 1966). A person may observe that others are afraid of certain objects or events and develop fears of those objects or events as well. Consider a young boy whose mother is afraid of illnesses, doctors, and hospitals. If she frequently expresses those fears, before long the boy himself may fear illnesses, doctors, and hospitals. Research has supported the theory that fears can be acquired through classical conditioning or modelling (Wilson, 2011).

TABLE 15.5

10 Most Common Phobias
Sources: Kaskas, Ryan, & Davis, 2017; Van Wagner, 2007; Melville, 1978.

Fear	Phobia Name
Spiders	Arachnophobia
Heights	Acrophobia
Public, social places	Agoraphobia (now included in anxiety disorder)
Social situations	Social phobia (now included in social anxiety disorder)
Flying	Aerophobia
Enclosed spaces	Claustrophobia
Thunder	Brontophobia
Germs	Mysophobia
Cancer	Carcinophobia
Death	Necrophobia

Panic Disorder

Sometimes an anxiety reaction takes the form of an all-consuming, nightmarish panic. Everyone reacts with panic when a real threat occurs and they feel endangered. Some people, however, experience **panic attacks**—periodic, discrete bouts of panic or terror—in the absence of any real threat. These attacks occur suddenly, as a wave of intense fear, reach a peak within 10 minutes, and gradually pass (see photo). Individuals who experience unexpected, repeated panic attacks suffer from **panic disorder**. People who experience these attacks report that they believe they are having a heart attack or losing their mind. Panic disorder is often accompanied by **agoraphobia**, a fear of venturing into public places, especially when alone. Because of their panic attack history, some sufferers of panic disorder develop a fear of travelling to any location where escape might be difficult or help unavailable should panic symptoms develop.

panic attacks periodic, short bouts of panic.

panic disorder an anxiety disorder characterized by recurrent and unpredictable panic attacks that occur without apparent provocation.

agoraphobia a phobia that makes people avoid public places or situations in which escape might be difficult or help unavailable should panic symptoms develop.

geotrac/Getty Images

Panic attack **Many people experience difficulty "catching their breath" during a panic attack, which can lead to hyperventilation.**

Around 4 percent of people in Canada over 15 years of age have suffered from a panic attack at some point in their lives (Canadian Mental Health Association, 2013; Ramage-Morin, 2004). The lifetime rate is highest (5.1 percent) among 45- to 55-year-olds, and lowest (2.5 percent) among those over 55 years of age. Women are nearly twice as likely than men to have experienced a panic attack in any given year (Scott et al., 2018).

As mentioned, neuroscientists have determined that emotional reactions are tied to brain circuits. Panic attacks appear to be produced in part by a brain circuit in the *amygdala*, *hypothalamus*, and *locus ceruleus* (Khalsa et al., 2016; Dresler et al., 2011). Many of today's researchers believe that this brain circuit—including *norepinephrine* and other neurotransmitters—probably functions improperly, producing an excess amount of norepinephrine in people who experience panic disorder (Nardi & Freire, 2016; Noel & Curtis, 2019).

According to cognitive theorists, not only are these individuals hypersensitive to changes in arousal, but once they experience particular bodily sensations, they tend to misinterpret the sensations as signs of a medical catastrophe and fear that the symptoms are signalling that something dire is about to occur (Gellatly & Beck, 2016; Reinecke et al., 2011; Wenzel, 2011a, 2011b). As a result, affected individuals become hypervigilant, fearing the signals

that indicate another attack, ceaselessly monitoring for them, and in so doing increase the likelihood they will experience another.

Obsessive-Compulsive Disorder

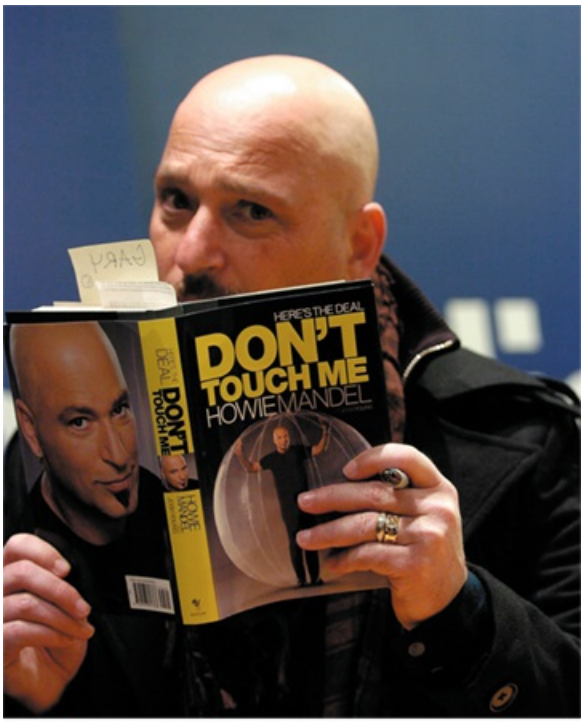
Obsessions are persistent thoughts, ideas, impulses, or images that seem to overrun a person's consciousness. **Compulsions** are repetitive and rigid behaviours or mental acts that people feel compelled to perform to prevent or reduce anxiety. A diagnosis of **obsessive-compulsive disorder (OCD)** is made when obsessions or compulsions are severe; are viewed by the person as excessive, unreasonable, or irrational; cause great distress; consume considerable time; or interfere with daily functions.

> **obsessions** persistent thoughts, ideas, impulses, or images that seem to invade a person's consciousness.
>
> **compulsions** irrational repetitive and rigid behaviours or mental acts that people feel compelled to perform to prevent or reduce anxiety.
>
> **obsessive-compulsive disorder (OCD)** a mental disorder associated with repeated, abnormal, anxiety-provoking thoughts and/or repeated rigid behaviours.

Compulsive acts are typically responses to ward off obsessive thoughts. One study found that in most cases of OCD, compulsions represent a *yielding* to obsessive doubts, ideas, or urges. For example, a woman who has obsessive fears of contamination may yield to that fear by performing cleaning rituals. The study also found that compulsions sometimes serve to *control* obsessions. A man with obsessive images of sexual events, for example, may try to control those images by filling his mind with compulsive verbal rituals, such as repeated expressions, phrases, or chants. In all such instances, the performance of the compulsive acts reduces the anxiety produced by obsessive thoughts.

Two percent of people in Canada suffer from obsessive-compulsive disorder in a given year (Osland, Arnold, & Pringsheim, 2018; Langlois et al., 2011). The disorder is equally common in men and women and among people of different races and ethnic groups (Mathes, Morabito, & Schmidt, 2019).

Obsessions often take the form of obsessive *wishes* (for example, repeated wishes that one's spouse would die), *impulses* (repeated urges to yell out obscenities at work or at a place of worship), *images* (fleeting visions of forbidden sexual scenes), or *doubts* (concerns that one has made or will make a wrong decision). Like obsessions, compulsions take various forms but serve to reduce the anxiety brought about by the obsession. For example, *cleaning compulsions* are very common. People with these compulsions feel compelled to keep cleaning themselves, their clothing, or their homes. The cleaning may follow ritualistic rules and be repeated dozens or hundreds of times a day, making it almost impossible to have a normal life (see photo).



Paul Lapid/The Canadian Press

Obsessive-compulsive disorder **Canadian comedian, game-show host, and author of the book *Don't Touch Me*, Howie Mandel has OCD and an irrational fear of germs (*mysophobia*). He will not shake hands with anyone (including contestants on the game show he used to host, *Deal or No Deal*) because of his fear of contamination.**

How Do Cognitive-Behavioural Theorists Explain Obsessive-Compulsive Disorder?

According to an early cognitive-behavioural theory, people stumble upon their compulsions by chance. In a fearful situation, they happen just coincidentally to wash their hands, say, or dress a certain way. When the threat lifts, they link the improvement to that particular action. After repeated accidental associations, they believe that the action is bringing them good luck or actually changing the situation. As a result, they perform the same action again and again in similar situations. The act becomes a way to avoid or reduce anxiety (Frost & Steketee, 2001).

Another cognitive-behavioural theory focuses on the relationship between obsessions and compulsions and suggests that people learn to perform compulsive acts specifically because such acts reduce the anxiety aroused by their obsessions. According to this theory, some people are generally more inclined than others to experience repetitive, unwanted, and intrusive thoughts, to blame themselves for such thoughts, and to expect that the thoughts can somehow cause terrible things to happen (DeRubeis et al., 2019). To avoid such negative outcomes, they learn to "neutralize" the thoughts—behave in ways meant to put matters right, make amends, and reduce their anxiety.

In support of this cognitive-behavioural explanation, studies have found that people diagnosed with obsessive-compulsive disorder do indeed experience intrusive thoughts

more often than other people, resort to more neutralizing strategies, and experience reductions in anxiety after using neutralizing techniques (Bouvard et al., 2017; Hezel & McNally, 2016). But why do certain people experience more intrusive thoughts in the first place?

How Do Neuroscientists Explain Obsessive-Compulsive Disorder?

The biological explanation of this disorder features two lines of brain research. One points to abnormally low activity of the neurotransmitter serotonin, and the other to abnormal activity in key brain structures.

Some antidepressant drugs help reduce obsessive and compulsive symptoms. Since these drugs also increase serotonin activity, some researchers have concluded that the disorder may be caused by low serotonin activity (Sinopoli, Burton, Kronenberg, & Arnold, 2017; Issaria et al., 2016; Abudy et al., 2012). In another line of research, investigators found a link between obsessive-compulsive disorder and abnormal functioning in specific regions of the brain. Particularly important are the *orbitofrontal cortex*, a region in the prefrontal cortex, and the *caudate nuclei*, structures located within the basal ganglia. These regions are part of a brain circuit that usually converts sensory information into thoughts and actions (Keshavan & Yeragani, 2018). Based on a variety of studies, many neuroscientists have come to believe that one or both of these brain regions are somewhat overactive in certain people, leading to a constant eruption of troublesome thoughts and actions (Ducharme, Dougherty, & Drevets, 2016; Endrass et al., 2011).

Additional parts of this brain circuit have been identified in recent years, including the *thalamus*, the *cingulate cortex*, the *striatum's caudate nucleus,* and, once again, the *amygdala.* It may be that these regions also play key roles in OCD. The serotonin and brain region abnormalities may be linked. It turns out that serotonin plays a very active role in the operation of the orbitofrontal cortex, caudate nuclei, and other structures in the brain circuit. Thus, low serotonin activity might well disrupt the proper functioning of those brain structures. The hypothesis is that the cingulated cortex and hypothalamus activate the OCD impulses that are inhibited though the caudate nucleus, while the amygdala drives the fear and anxiety components of the OCD response (Barrios-Anderson & McLaughlin, 2020).

Posttraumatic Stress Disorder (PTSD)

Stress reactions, and the sense of fear they produce, are often at play in psychological disorders. As you have seen, for example, people who experience a large number of stressful events are particularly vulnerable to the onset of depression. In addition, stress plays a more central role in *acute stress disorder* and *posttraumatic stress disorder* (*PTSD*).

Symptoms of Acute Stress Disorder and Posttraumatic Stress Disorder

Chapter 14 described the roles of the *autonomic nervous system (ANS)* and the *hypothalamic-pituitary-adrenal (HPA)* axis during everyday stress reactions. If people experience a threatening situation where they witness a death or there is the threat of death or injury or sexual violence, they experience levels of arousal, anxiety, and depression that are far beyond those experienced with everyday stress reactions. For

example, Canadian soldiers who served in Afghanistan and residents of Quebec City who were close to a fatal shooting at a mosque are all candidates for PTSD (see photos).

(left) Printed by permission of Random House Canada (right) Ryan Remiorz/ZUMA Press/Newscom

Many events can produce PTSD **Roméo Dallaire wrote about his experiences as Canada's highest ranking officer in Rwanda in his book *Shake Hands with the Devil: The Failure of Humanity in Rwanda* (left). Dallaire, a retired Canadian senator, is working to raise awareness of the atrocities of war and of PTSD. The shootings at a Quebec City mosque in January 2017 (right) shocked Canadians and put those close to it at risk for symptoms of PTSD.**

For most people, the panic reactions subside soon after the danger passes. But for others, the feelings of anxiety and depression, as well as other symptoms, persist well after the overwhelmingly distressful situation is over. These people are suffering from *acute stress disorder* or *posttraumatic stress disorder*, patterns that arise in reaction to a psychologically traumatic event with life-threatening implications, such as witnessing a murder, combat, rape, earthquake, airplane crash, or traffic accident.

If the lingering stress symptoms begin within four weeks of the traumatic event and last for less than a month, a diagnosis of **acute stress disorder** is made (APA, 2013). If the symptoms continue longer than a month, a diagnosis of **posttraumatic stress disorder (PTSD)** is given. The symptoms of PTSD may begin either shortly after the traumatic event or months or even years afterward (Waller et al., 2016). Studies indicate that many cases of acute stress disorder develop into PTSD (Bryant, 2018; Haag, Robinaugh, Ehlers, & Kleim, 2017). Aside from the differences in onset and duration, the symptoms of acute stress disorder and PTSD are almost identical. The individuals experience high levels of ongoing anxiety and depression. They may feel overly alert (hyper alertness), be easily startled, have trouble concentrating, and develop sleep problems (Friedman, 2015; Ruzek et al., 2011). They may also feel extreme guilt because they survived the traumatic event while others did not.

acute stress disorder an anxiety disorder in which fear and related symptoms are experienced soon after a traumatic event and last less than a month.

posttraumatic stress disorder (PTSD) an anxiety disorder in which fear and related symptoms continue to be experienced long after a traumatic event.

In addition, people with stress disorders may be besieged by recurring thoughts, memories, dreams, or nightmares connected to the traumatic event (Birkeland & Heir, 2017). They typically avoid all activities that remind them of the event and try to ignore related thoughts, feelings, or conversations. Affected individuals often also feel detached from other people or lose interest in activities that once brought enjoyment. They may feel dazed and have trouble remembering things (Keane, Marx, Sloan, & DePrince, 2014).

Michael Anton Van Ameringen, at McMaster University, and his colleagues conducted an incidence study looking at stress disorders in Canada. They found a lifetime PTSD prevalence of 9.2 percent in their Canadian sample, as well as a current (at the time of the survey) incidence of 2.4 percent (Peterlin et al., 2011; Taylor, 2010a, 2010b; Van Ameringen, Mancini, & Patterson, 2011). Women are at least twice as likely as men to develop stress disorders: around 20 percent of women who are exposed to a serious trauma may develop one, compared to 8 percent of men (Olff, 2017). Refugees often struggle with issues related to past traumas though, for some, finding a new home supports Posttraumatic Growth. Find out about this in Positive Psychology 15.2.

What Causes a Stress Disorder?

Clearly, extraordinary trauma can cause a stress disorder. The stressful event, however, is not the entire explanation. Certainly, anyone who experiences an unusual trauma will be affected by it, but only some people develop acute stress disorder or posttraumatic stress. To more fully explain the onset of these disorders, researchers point to individuals' biological processes, personalities, childhood experiences, social support systems, and cultural backgrounds.

Biological and Genetic Factors Investigators have learned that traumatic events often trigger physical changes in the brain and body that may lead to severe stress reactions and, in some cases, to stress disorders. They have found, for example, abnormal activity of the hormone *cortisol* and the neurotransmitter *norepinephrine* in the urine, blood, and saliva of combat soldiers, rape victims, concentration camp survivors, and survivors of other severe stresses (Duncan, Cooper, & Shen, 2018).

Evidence from brain studies also shows that once a stress disorder begins, individuals experience further biochemical arousal, and this continuing arousal may eventually damage key brain areas, particularly the hippocampus and the *amygdala* (Akiki et al., 2017; Morey et al., 2016).

Personality Some studies suggest that people with certain personalities, attitudes, and coping styles are particularly likely to develop stress disorders (Meyer, La Bash, et al., 2019). Research has also found that people who generally view life's negative events as beyond their control tend to develop more severe stress symptoms after experiencing a stillbirth or live combat than people who feel greater control over their lives (Chung & Reed, 2017; Mikaeili, Einy, & Taghavy, 2018).

Childhood Experiences Investigators have found that certain childhood experiences seem to leave some people at risk for later acute and posttraumatic stress disorders.

People whose childhoods have been marked by poverty appear more likely to develop these disorders in the face of later trauma. So do people whose family members suffer from psychological disorders; who experienced assault, abuse, or catastrophe at an early age; or who were younger than 10 when their parents separated or divorced and therefore have not yet developed the means to cope with such foundational life changes (Schalinski et al., 2016; Murphy et al., 2014).

Social Support It has been found that people whose social and family support systems are weak are also more likely to develop a stress disorder after a traumatic event. Rape victims who feel loved, cared for, valued, and accepted by their friends and relatives recover more successfully than do those without those supports (Bryant-Davis et al., 2015; Uchino & Birmingham, 2011). So do those treated with dignity and respect by the criminal justice system (Patterson & Tringali, 2015; Patterson, 2011).

15.2 Psychology Around Us | Positive Psychology

Posttraumatic Growth and Canadian Refugees

As you have read in several places in this textbook, posttraumatic stress disorder (PTSD) is real, and can be a very debilitating disorder that can impact people for the rest of their lives after the triggering event. Researchers have shown for decades that PTSD is a challenge for refugees to cope with and try to overcome once they are in locations of relative safety, regardless of where they live (Ahmad, Othman, & Lou, 2019; Reavell & Fazil, 2017; Ssenyonga, Owens, & Olema, 2013). In the last decade, attention has been focused on the mental health of child and adult refugees who have resettled in Canada. We know that factors such as providing community support to refugees, preventing discrimination against them, and giving them a sense of safety are critical for coping with the PTSD they often experience from the traumas of living in often war-torn countries, escaping their countries of origin, and settling in a new, unfamiliar, country.

While PTSD has been well-documented in the literature on refugee mental health, another phenomenon, called posttraumatic growth (PTG), can also occur in some refugees, especially when they can make logical sense of their trauma experiences. The reflection of some refugees on the process of resettlement can lead to intra- and interpersonal gains, and these gains are influenced by their personality traits, such as optimism, their coping style, and positive community support (Chan, Young, & Sharif, 2016). Improvements in mental health function, and PTG in refugees, depends on the support we give our refugees as they adjust to Canadian society, schools, and places of employment (Walker & Zuberi, 2020). It may be that these individuals' PTG—their outlook of hope and their resilience—will be the most important factor for their personal success and for combatting the PTSD they may be experiencing (Tweedie, Belanger, Rezazadeh, & Vogel, 2017).

George Rose/Getty Images

Refugees Can Experience Posttraumatic Growth **Many refugees who have experienced past trauma can, once they get resettled, experience Posttraumatic Growth and thrive in their new location.**

Many of these factors associated with PTSD can clearly be seen in the lives and circumstances of members of the Canadian military returning home from service abroad (Watkins, Sudom, & Zamorski, 2016). In March 2001, in what may have been a suicide attempt, Corporal Christian McEachern drove his SUV directly into the headquarters building at CFB Edmonton. Corporal McEachern had served with Canada's peacekeeping forces in Croatia and Uganda and had been diagnosed with PTSD upon his return. He was eventually tried for this action and found guilty, but was given no jail time. His complaint about the lack of proper services for Canadian Armed Forces members struggling with PTSD was investigated by Canada's parliamentary ombudsman. The ombudsman found that many cases of PTSD among Canada's military personnel were going unidentified and untreated (Marin, 2001). A follow-up report in 2008 found that 18 of the 31 recommendations in the original report had not yet been implemented (McFadyen, 2008). There are simply not enough treatment providers to meet the needs of veterans who struggle with PTSD in Canada (MacLeod & Leduc, 2019; Brewster, 2012). (See Indigenous Experiences 15.2.)

15.2 Indigenous Experiences

Multigenerational and Intergenerational Trauma

Multigenerational and *intergenerational trauma* occurs when untreated trauma-related stress is passed from survivors to members of their families in successive generations. Typically, intergenerational trauma occurs in a family where damaging emotional neglect and abuse traumatized either or both of a parent or grandparent but was not resolved in that generation. As a consequence, when these individuals became parents, these collective experiences began to accumulate and subsequent generations

of the family came to understand, cope with, and heal (or fail to heal) from the original trauma or ensuing trauma(s) (FCSS, 2012).

In Canada, historical injustice and oppression against Indigenous peoples has a long and grim history and encompasses the residential school experience which, as we now know, was largely designed to force assimilation, break the bonds between children and their families, and abolish Indigenous cultures. Thus, one of the legacies of the residential school system has been systemic, intergenerational trauma, in the form of ongoing mental and physical health issues, loss of identity, systemic racism, bigotry and discrimination, family dysfunction, poverty, addiction, incarceration, and cultural breakdown. On an individual level, as discussed throughout the text, many survivors of the residential school system suffered trauma while in residential schools as children and continue to suffer from a broad range of mental and physical health issues as a result of that trauma (Gone et al., 2019; McQuaid et al., 2017). These issues are in turn amplified or distorted over subsequent generations as maladaptive patterns of behaviours the survivors used to protect themselves from the abuse they suffered become entrenched and are then passed down to their own children and grandchildren, often unconsciously (Igloliorte, 2010). George Amato, who attended the St. Bernard school in Alberta, says, "How are we supposed to know how to be a parent when you don't have guidance from anybody? All I had in me all my life was anger" (Truth and Reconciliation Commission of Canada, 2012, p. 79).

Trauma is subjective and results from circumstances that outweigh a person's ability to cope. Thus, responses to seemingly similar devastating events are highly individualistic. In some cases, children were able to remain resilient, in spite of very traumatizing circumstances. Take Lillian Elias. She attended a Residential School in Aklavik, Northwest Territories from the time she was about eight years old. From the outset, she secretly maintained her Inuvialuktun language, which helped her to maintain ties with her culture and her home. She says, "I always say that your culture, your language, tradition, if you have those three you feel good about yourself" (Igloliorte, 2010, p. 58). A resilient survivor, she and her husband kept their own children out of the schools. "My children never stepped in a Residential School because their father wouldn't let them. He was there too long" (p. 55). Other survivors may not be able to begin the process of healing until they are adults, but then begin to recognize the fear and shame, rebuild their family systems, and address the cultural losses stemming from their residential school experiences. When Velma Page was asked in what ways she felt residential schooling may have affected her as a mother, she replied, "A lot of ways. I never learnt how to be friendly or have friends… But I don't see none of my kids. They don't phone or want to visit me… I guess that's the way I brought them up and now I've learned that's the way they are" (Legacy of Hope Foundation, 2020). Culturally appropriate ways to heal these intergenerational rifts are being developed and will be addressed in the next chapter.

Recognizing the impact of intergenerational trauma **Residential school survivors are honoured in a walk by First Nations members in Vancouver, British Columbia.**

Critical Thinking Questions

What do multigenerational and intergenerational trauma involve and how are they related to residential school experiences?

How are individual residential school experiences related to trauma in subsequent generations and why do these impacts vary across individuals?

What sorts of factors are involved in coping and resilience among residential school survivors and their own children?

Before You Go On

(Answers to Before You Go On may be found online in the Course Resources.)

What Do You Know?

11. What are six types of anxiety disorder?

12. How and why might generalized anxiety disorder be related to uncertainty?

13. What role do conditioning and modelling play in the development of phobias?

14. What individual factors affect who will develop posttraumatic stress disorder?

What Do You Think? • The return home for many soldiers is often difficult. One of the problems they face is trying to find a way to talk about their experiences with friends and relatives; if you haven't experienced war, there's really no way to understand what soldiers go through. What sorts of things can we do to make the return home easier for Canadian soldiers?

Schizophrenia

LEARNING OBJECTIVE 5

Describe the features of schizophrenia and some theories of what causes it.

Schizophrenia is a psychotic disorder in which people deteriorate into a world of distorted perceptions, disturbances in thoughts, emotions, behaviours, and experience motor abnormalities. People with this disorder experience **psychosis**, a loss of contact with reality. Their ability to perceive and respond to the environment becomes so disturbed that they may not be able to function at home, with friends, in school, or at work. They may have *hallucinations* (false sensory perceptions) or *delusions* (false beliefs), or they may withdraw into a private world. Psychosis is most commonly associated with schizophrenia, but a number of other disorders may feature psychotic symptoms, such as bipolar disorder or postpartum depression.

schizophrenia a mental disorder characterized by disorganized thoughts, lack of contact with reality, and sometimes hallucinations.

psychosis loss of contact with reality.

Approximately 1 of every 100 people in the world suffers from schizophrenia during his or her lifetime. Equal numbers of men and women receive this diagnosis (Riecher-Rössler, Butler, & Kulkarni, 2018). Almost 3 percent of all those who are divorced or separated suffer from schizophrenia over the course of their lives, compared with 1 percent of married people and 2 percent of people who remain single (Miller & Mason, 2011).

Victor de Schwanberg/Science Source

Hallucinations **Hallucinations are one positive symptom of schizophrenia.**

According to the DSM-5, schizophrenia is diagnosed when a minimum of two symptoms appear continuously for one month and last for six months or more. The symptoms of schizophrenia can be grouped into three categories: *positive symptoms*, *negative symptoms*, and *cognitive symptoms. Psychomotor symptoms* are also often considered in diagnosis. What is it like to drift into psychosis? Rachel Aviv wrote a compelling article on peoples' experiences with their own and close others' schizophrenia symptoms for *Harper's* magazine. You can read the article here: www.columbia.edu/cu/neuwrite/pubs/avivHarpers.pdf.

Positive Symptoms of Schizophrenia

Positive symptoms are "pathological excesses," or bizarre additions, to a person's behaviour and are not seen in people who do not have the disorder. *Delusions*, *disorganized thinking and speech*, *hallucinations*, and *inappropriate affect* are the ones most often found in schizophrenia (see photo).

> **positive symptoms** in the case of schizophrenia, symptoms that seem to represent pathological excesses in behaviour, including delusions, disorganized thinking and speech, hallucinations, and inappropriate affect.

Delusions are false beliefs that are resistant to reason or contradictory evidence, but are maintained in spite of their irrationality. *Delusions of persecution* are the most common delusions in schizophrenia (APA, 2013). People with this delusion believe they are being plotted or discriminated against, spied on, slandered, threatened, attacked, or deliberately victimized. Delusions of identity also occur; for example, the person with schizophrenia believes that he or she is Jesus Christ or Winston Churchill. People with *delusions of grandeur* often believe that they have some special talent or that they are privy to secret knowledge (for example, they have the ability to fly or know that the United States is planning to infiltrate Canada).

> **delusions** blatantly false beliefs that are firmly held despite evidence to the contrary.

People with schizophrenia may also exhibit *disorganized thinking and speech*. Many, for example, display **loose associations**, or **derailment**: they rapidly shift from one topic to another, believing that their incoherent statements make sense. One man with schizophrenia, asked about his itchy arms, responded:

> *The problem is insects. My brother used to collect insects. He's now a man 5 foot 10 inches. You know, 10 is my favourite number. I also like to dance, draw, and watch television.*

> **loose associations** or **derailment** a common thought disorder of schizophrenia, characterized by rapid shifts from one topic to another.

Individuals with schizophrenia may also experience **hallucinations**, perceptions that occur in the absence of external stimuli. People who have *auditory hallucinations*, by far the most common kind in schizophrenia, hear sounds and voices that seem to come from outside their heads (APA, 2013).

> **hallucinations** imagined sights, sounds, or other sensory events experienced as if they were real.

Yet another positive symptom found in schizophrenia is *inappropriate affect*, emotions that are unsuited to the situation. The individuals may smile when making a serious statement or on being told terrible news, or they may become upset in situations that should make them happy. They may also undergo inappropriate shifts in mood.

Negative Symptoms of Schizophrenia

Negative symptoms are those that seem to be "pathological deficits," characteristics that are lacking in an individual but that are seen in individuals without the disorder. *Poverty of speech*, *flat affect*, *loss of volition*, and *social withdrawal* are commonly found in schizophrenia.

> **negative symptoms** in the case of schizophrenia, symptoms that seem to reflect pathological deficits, including poverty of speech, flat affect, loss of volition, and social withdrawal.

Poverty of speech refers to a reduction in speech or speech content. Some people with this negative symptom think and say very little. Others say quite a bit but still manage to convey little meaning. In another negative symptom, *flat affect*, individuals show very little anger, sadness, joy, or other feelings. The faces of these persons are still, their eye contact poor, and their voices monotonous.

Still other persons experience *avolition*, or apathy. They feel drained of energy and interest in normal goals and are unable to start or follow through on a course of action. And, in yet another negative symptom, people with this disorder may *withdraw* from their social environment and attend only to their own ideas and fantasies. Because their ideas are illogical and confused, withdrawal helps distance them still further from reality (Galderisi, Mucci, Buchanan, & Arango, 2018; Marder & Galderisi, 2017; Leucht & Davis, 2017).

Catatonic posturing **Some people struggling with schizophrenia demonstrate catatonic posturing, where they strike and hold bizarre positions, sometimes for hours.**

Cognitive Symptoms of Schizophrenia

Cognitive impairment is a core feature of schizophrenia and affects most individuals diagnosed with the disorder. Affected cognitive functions include memory, executive function, attention, working memory, and intelligence. Undetected cognitive deficits exist and generally pre-date diagnosis of the illness (Seccomandi et al., 2020). Social and functional outcome is related to the degree of cognitive impairment (Green, Horan, & Lee, 2019). Cognitive deficits are related to brain tissue changes and are consequently permanent, persisting even during symptom remission; it is therefore imperative that

patients remain on their antipsychotic medications (Nuechterlein et al., 2013).

Psychomotor Symptoms of Schizophrenia

People with schizophrenia sometimes experience unusual *psychomotor symptoms*—they may move awkwardly or make odd grimaces and gestures. The gestures often seem to have a private, perhaps ritualistic, purpose. The psychomotor symptoms may take extreme forms, collectively called **catatonia**. People in a *catatonic stupor*, for example, stop responding to their environment, remaining motionless and silent for long stretches of time. Others exhibit *catatonic rigidity*, maintaining a rigid upright posture for hours and resisting efforts to be moved. Still others display *catatonic posturing*, assuming awkward, bizarre positions (a squatting position, for example) for long periods of time (see photo). They may even exhibit *waxy flexibility*, in which they maintain indefinitely postures into which they have been placed by someone else (Weinberger & Harrison, 2011).

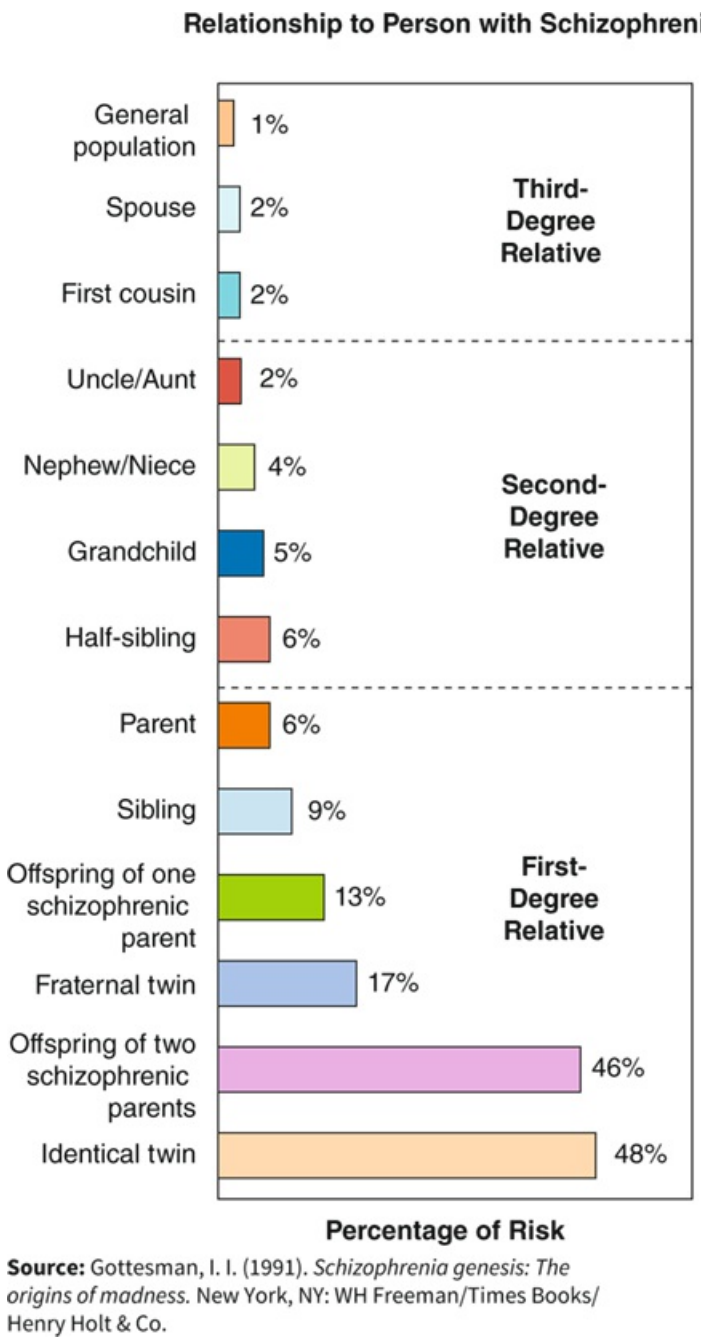
> **catatonia** extreme psychomotor symptoms of schizophrenia, including catatonic stupor, catatonic rigidity, and catatonic posturing.

How Do Neuroscientists Explain Schizophrenia?

Biological explanations of schizophrenia have received the most research support. This is not to say that psychological and socio-cultural factors play no role in the disorder. Rather, it has been hypothesized that a diathesis-stress relationship may account for the development of schizophrenia: perhaps people with a biological predisposition develop schizophrenia only if certain kinds of psychological events, personal stress, or societal expectations are also present.

Genetic Factors

Many theorists believe that people inherit a genetic predisposition to schizophrenia (Swathy & Banerjee, 2017; Leo, 2016; Akbarian, 2010). In support of this notion, studies have found repeatedly that schizophrenia is more common among relatives of people with the disorder than among other individuals (Lo, Kaur, Meiser, & Green, 2020). The more closely related the relatives are to the person with schizophrenia, the greater their likelihood of developing the disorder (see **Figure 15.4**).



Source: Gottesman, I. I. (1991). *Schizophrenia genesis: The origins of madness.* New York, NY: WH Freeman/Times Books/ Henry Holt & Co.

FIGURE 15.4 Family connections and schizophrenia **Biological relatives of people with schizophrenia have a higher risk than the general population of developing the disorder during their lifetimes. Closer relatives (who have a more similar genetic makeup) have a greater risk than more distant relatives.**

Researchers have been particularly interested in twins. If both members of a pair of twins have a particular trait, they are said to be *concordant* for that trait. Therefore, if genetic factors are at work in schizophrenia, identical twins (who share most genes) should have a higher concordance rate for this disorder than *fraternal twins* (who share only about 50 percent of their genes). This expectation has been supported by research (Hilker et al.,

2018; Kläning et al., 2016; Higgins & George, 2007). Studies have found that if one identical twin develops schizophrenia, there is a 48 percent chance that the other twin will also develop schizophrenia at some point in his or her life. If the twins are fraternal, on the other hand, the second twin has approximately a 17 percent chance of developing the disorder. Considerable evidence suggests also that infection in the prenatal and perinatal environments plays an important role in the etiology of schizophrenia (Rubesa, Gudelj, & Makovac, 2018).

How might genetic factors lead to the development of schizophrenia? Research has pointed to two kinds of brain abnormalities that may be inherited—*biochemical abnormalities* and *abnormal brain structures*.

Biochemical Abnormalities

Over the past four decades, researchers have developed the *dopamine hypothesis* to help explain schizophrenia. The first clue that high dopamine activity may contribute to schizophrenia came with the accidental discovery in the 1950s of **antipsychotic drugs**—medications that help remove the symptoms of schizophrenia (Garver, 2006; Healy, 2005). Originally used as anesthetics during surgery, the early drugs were found to also calm agitated psychotic patients. Direct tests followed, and a revolution in the treatment of schizophrenia began (Ban, 2007).

antipsychotic drugs medications that help remove the symptoms of schizophrenia.

The dopamine hypothesis proposes a dysregulation or imbalance of dopamine with a hyperactive (overactive) subcortical transmission resulting in positive symptoms, and a hypoactive (underactive) cortical transmission to prefrontal cortex resulting in cognitive impairments and negative symptoms (Howes et al., 2017; Gründer & Cumming, 2016; Edwards et al., 2016). This hypothesis has undergone challenges and adjustments in recent years, but it is still the foundation for present biochemical explanations of schizophrenia. Additional studies further suggest that abnormal activity of the neurotransmitters glutamate and serotonin may also play a role in schizophrenia (Stahl, 2018; Gillespie et al., 2017).

Abnormal Brain Structures

During the past decade, researchers have also linked many cases of schizophrenia to abnormalities in brain structure (Nelson et al., 2017; Birur, Kraguljac, Shelton, & Lahti, 2017; Brugger & Howes, 2017). Using brain scans, for example, they have found that many people with schizophrenia have enlarged ventricles (the brain cavities that contain cerebrospinal fluid), relatively small temporal lobes and frontal lobes, and abnormal blood flow in certain areas of the brain. In addition, some studies have linked schizophrenia to structural abnormalities of the hippocampus, amygdala, and thalamus (Edwin-Thanarajah et al., 2016).

Before You Go On

(Answers to Before You Go On may be found online in the Course Resources.)

What Do You Know?

15. What is a psychosis?

16. What are the positive symptoms of schizophrenia? The negative symptoms? The psychomotor symptoms?

17. What biochemical abnormalities and brain structures have been associated with schizophrenia?

What Do You Think? • We noted in this section that if one identical twin develops schizophrenia, there is a 48 percent chance that the other twin will do so as well. Discuss how this might support the diathesis-stress perspective.

Other Disorders

LEARNING OBJECTIVE 6

Discuss the features and possible causes of somatic symptom and related disorders, dissociative, and personality disorders.

We have now examined three important categories of psychological disorders: mood disorders, anxiety disorders, and schizophrenia. We will conclude the chapter by looking briefly at three additional disorder categories: somatic symptom and related disorders, dissociative disorders, and personality disorders.

Somatic Symptom and Related Disorders

The DSM-5 identifies **somatic** (physical) **symptom and related disorders** as defined by excessive concerns about physical health. Unlike the DSM-IV-TR, where the diagnosis required that the disorders be medically unexplained, the DSM-5 has removed this criterion. The DSM-5 includes somatic symptoms whether they can be medically explained or not. People with somatic symptom and related disorders often seek medical treatment, visiting numerous physicians and taking many different types of medications. Repeated hospitalization and surgeries are common. This behaviour is costly to the individual and to society. Frequently no medical explanation or cure is available to explain their symptoms. Typically these individuals do not consciously want or purposely produce their symptoms; they believe that their problems are genuine and experience the symptoms as completely physical (McGeary et al., 2017; American Psychiatric Association Division of Research, 2013).

> **somatic symptom and related disorders** excessive thought, feelings, and behaviours related to somatic symptoms.

There are five specific diagnoses related to somatic symptom and related disorders: somatic symptom disorder, illness anxiety disorder, conversion disorder (functional neurological symptom disorder), psychological factors affecting other medical conditions,

and factitious disorder.

Zinkevych/Getty Images

Somatic symptoms? People with somatic symptom disorder spend a lot of time seeking medical assistance with symptoms that often elude diagnosis.

Somatic Symptom Disorder

The DSM-5 has three criteria for somatic symptom disorder (SDD): (1) the individual has one or more somatic symptoms that cause distress or significant disruption in their daily life; (2) excessive health-related anxiety and concern, as well as time and energy, are devoted to the somatic complaint; and (3) the concern has lasted for at least six months. For some, pain is of central concern.

Ailments may include pain symptoms (such as headaches and chest pain), gastrointestinal symptoms (such as nausea and diarrhea), sexual symptoms (such as erectile or menstrual difficulties), and neurological symptoms (such as double vision or paralysis). Sufferers may go from doctor to doctor in search of relief (see photo). Some may even seek multiple surgical procedures. They often describe their many symptoms in dramatic and exaggerated terms (Henningsen, 2018; Kurlansik & Maffei, 2016).

Illness Anxiety Disorder

In this disorder, an individual is preoccupied with having a serious disease in spite of the lack of somatic symptoms (Shikatani, Nowakowski, & Antony, 2015). To meet the DSM-5 criteria, the personmust engage in excessive care-seeking for at least six months and engage in excessive illness behaviours. It is important to note that a person must have minimal or no symptoms to meet this diagnosis. If symptoms are present, the person would be diagnosed with somatic symptom disorder.

Conversion Disorder: Functional Neurological Symptom Disorder

In *conversion disorder*, a person develops symptoms suggestive of neurological damage, such as paralysis, seizures, blindness, or loss of feeling. Symptoms may also include muscle tensing, arm or leg twitching, shaking or barking, and other odd behaviours (Levenson &

Sharpe, 2017; Ding & Kanaan, 2017; Nicholson et al., 2016). However, medical tests suggest that the bodily systems and central nervous system are healthy. The symptoms usually appear suddenly, at times of extreme stress, and last a matter of weeks. The disorders are thought to be quite rare, occurring in at most 5 of every 1,000 persons (Abbey, 2005). The affected person appears almost unconcerned by the symptoms.

Conversion disorder is difficult to distinguish from *malingering* (Yakobov, Jurcik, & Sullivan, 2017). When people are malingering, they intentionally lie about symptoms to avoid an unwanted responsibility. This intentionality is not considered a part of conversion disorder. In general, malingers stand to benefit from their "illnesses" in some way (get out of a job or military service, receive a substantial insurance settlement, and so on) and, unlike those with conversion disorder, show an almost exaggerated interest in their symptoms.

Psychological Factors Affecting Other Medical Conditions

In psychological factors affecting other medical conditions, psychological factors affect a documented medical condition in an adverse manner, creating unique health risks (e.g., chronic overeating creating a lack of adherence to a medical protocol for diabetes) or delaying recovery and/or exacerbate (worsen) an existing medical condition (e.g., anxiety triggering asthma attacks).

Factitious Disorder

In factitious disorder, people deliberately assume physical or psychological symptoms to adopt the patient role (Bass & Halligan, 2014). Patients may lie about symptoms or they may actually take steps to make themselves ill, impaired, or injured—swallowing or injecting damaging drugs or substances to become genuinely ill or causing themselves bodily harm in some way. Factitious disorder can also be diagnosed in parents who fabricate illness in their children and then present them as ill, impaired, or injured. In this case the diagnosis is *factitious disorder imposed on another* (or *Munchausen by proxy*). Most cases of factitious disorder imposed on another involve a parent making a child ill; however, the diagnosis would hold in any instance where one person deliberately causes harm to another and then presents the other person as ill and themselves as caregiver.

What Causes Somatic Symptom and Related Disorders?

Although this specific categorization is relatively new, theorists have typically explained somatization disorders much as they explain anxiety disorders (Ferri, 2016; Bouman, 2008; Noyes, 2008). Behaviourists, for example, believe that the fears found in the disorders are acquired through classical conditioning or modelling (Marshall et al., 2007). Cognitive theorists suggest that people with one of these types of disorders are extremely sensitive to bodily cues and come to misinterpret them (Riebel, Egloff, & Witthöft, 2014; Witthöft & Hiller, 2010).

How Do Socio-Cultural Theorists Explain Somatic Symptom and Related Disorders?

Clinicians often use the term *somatization* when referring to the development of somatic symptoms in response to personal distress, the key feature of somatic symptom and related

disorders. Somatization of any kind is considered inappropriate in Western countries (Fritzsche, 2020). Some theorists believe, however, that this position reflects a bias held by Western clinicians—a bias that sees somatic symptoms as an *inferior* (developmentally immature) way of dealing with emotions.

A worldwide view reveals that the transformation of personal distress into somatic complaints is in fact the norm in many non-Western cultures (Koh, 2018; Holster, Hawks, & Ostermeyer, 2017; Kirmayer & Ryder, 2016). In such cultures, somatization is viewed as a socially and medically correct—and less stigmatizing—reaction to life's stressors. Studies have found very high rates of somatization in non-Western medical settings throughout the world, including China, Japan, and Arab countries (Matsumoto & Juang, 2016). Individuals in Latin countries seem to display the greatest number of somatic symptoms (Lanzara, Scipioni, & Conti, 2019; Kleinstäuber & Rief, 2017). Even within North America, people from Hispanic cultures display more somatic symptoms in the face of stress than do other populations. Such findings remind us once again that reactions to life's stressors are often influenced by culture. Overlooking this point can lead to knee-jerk mislabels or misdiagnoses.

Dissociative Disorders

People sometimes experience a major disruption of their memory. They may, for example, lose their ability to remember new information that they just learned or old information they once knew well. When such a change in memory lacks a physical cause, it is called a **dissociative disorder**. Part of a person's cognition or experience is no longer consciously accessible, and this aspect of memory seems to be *dissociated*, or separated, from the rest (Carlson et al., 2018; Wolf et al., 2014; Barlow, 2011). (See photo.) The DSM-5 includes three major dissociative disorders: dissociative amnesia, depersonalization/derealization disorder, and dissociative identity disorder. Although dissociative disorders are often portrayed in novels, movies, and television shows, they are in fact quite rare (Kate, Hopwood, & Jamieson, 2020; Brand & Frewen, 2017).

> **dissociative disorder** a psychological disorder characterized by major loss of memory without a clear physical cause; types include *dissociative amnesia*, *dissociative fugue*, and *dissociative identity disorder*.

GMint/Getty Images

Memory loss **All of us have problems remembering something from time to time, but those with dissociative disorders have major disruptions in memory where one part of their memory seems to be dissociated from the rest.**

Dissociative Amnesia

People with *dissociative amnesia* are unable to recall important information, usually of an upsetting nature, about their lives (APA, 2013). The loss of memory is much more extensive than normal forgetting and is often triggered by a traumatic event, as in wartime and natural disasters (Staniloiu et al., 2020; Staniloiu & Markowitsch, 2014). In most cases, the forgotten material or events eventually return, often without the help of treatment.

The memory loss generally focuses on a particular aspect of a traumatic experience rather than an entire period of time surrounding the event. For example, a person might not be able to recall the death of a child, but would recall other events that happened during that time. Usually dissociative amnesia is characterized by sudden onset of an episode with an equally rapid disappearance.

In a type of amnesia known as *fugue*, memory loss is extensive. People not only forget their personal identities and details of their past lives, but may also flee to an entirely different location. Some individuals travel a short distance and make few social contacts in the new setting (APA, 2013). In other cases, however, the person may travel far from home, take a new name, and establish a new identity, new relationships, and even a new line of work (APA, 2013). It ought to be noted that even for those who experience exceptionally traumatizing events, fugue is rare (Staniloiu & Markowitsch, 2014; Spiegel et al., 2012).

Depersonalization/Derealization Disorder

In depersonalization/derealization disorder, stress alters perceptions. Memory is unaffected, but the person becomes detached from the body and/or the self. Patients report feeling as if they are observing themselves from a vantage point outside the body, or report feeling robotic or viewing parts of their bodies as bizarre and unrelated to themselves. This disorder usually has an onset in adolescence and it can begin suddenly or gradually. Once it begins, it is chronic and can last for decades (Lynn et al., 2015; Hunter, 2013).

Dissociative Identity Disorder

People with *dissociative identity disorder*, previously known as *multiple personality disorder*, develop two or more distinct personalities—called *subpersonalities* or *alternate personalities*—each with a unique set of memories, behaviours, thoughts, and emotions. At any given time, one of the subpersonalities takes centre stage and dominates the person's functioning (Lynn et al., 2015; Barlow, 2011). Cases of dissociative identity disorder were first reported almost three centuries ago (Rieber, 2006, 2002). Women receive this diagnosis at least three times as often as men (APA, 2013).

How Do Psychodynamic Theorists Explain Dissociative Disorders?

A variety of theories have been proposed to explain dissociative disorders. Psychodynamic theorists believe that dissociative disorders are caused by *repression*, the most basic ego defence mechanism. As you read in Chapter 12, psychodynamic theorists believe that people fight off anxiety by unconsciously preventing painful memories, thoughts, or impulses from reaching awareness. Everyone uses repression to a degree, but people with dissociative disorders are thought to repress their memories excessively (Gupta & Kumar, 2018; Howell & Itzkowitz, 2016; Jha & Sharma, 2015). In the psychodynamic view, dissociative amnesia and fugue are *single episodes* of massive repression. In each of these disorders, a person unconsciously blocks the memory of an extremely upsetting event to avoid the pain of facing it. Repression may be their only protection from overwhelming anxiety (Kikuchi et al., 2010).

In contrast, dissociative identity disorder is thought to result from a *lifetime* of excessive repression (Howell & Itzkowitz, 2016; Howell, 2011). Psychodynamic theorists believe that continuous use of repression is motivated by traumatic childhood events, particularly abusive parenting. Children who experience such traumas may come to fear the dangerous world they live in and take flight from it by pretending to be another person who is looking on safely from afar. Abused children may also come to fear the impulses that they believe are the reasons for their excessive punishments. Whenever they experience "bad" thoughts or impulses, they unconsciously try to disown and deny them by assigning them to other personalities (Krüger & Fletcher, 2017; Baker, 2010).

The psychodynamic explanation has failed to receive much research support (Merenda, 2008). Most of the support for the psychodynamic position is drawn from case histories, which report brutal childhood experiences (Becker, Karriker, Overkamp, & Rutz, 2018). Yet some individuals with dissociative identity disorder do not report on abuse in their backgrounds. Moreover, child abuse is more common than dissociative identity disorder. This has left many critics asking why, if the psychodynamic explanation has merit, only a small fraction of abused children develop this disorder.

How Does the Neuroscience Approach Explain Dissociative Disorders?

The biological approach has nothing definitive in this area, but there have been a number of intriguing findings in recent years (Frewen & Lanius, 2015). For example, one study used MRI scans to examine the hippocampus and amygdala of individuals with and without dissociative disorder. Both of these brain regions were found to be significantly smaller in those with dissociative disorder. As well, these same regions have been found to be smaller in individuals with histories of childhood trauma (Fosse, Moskowitz, Shannon, & Mulholland, 2019). Other studies have shown decreased functioning in several emotional processing areas of the brains of individuals struggling with dissociative disorders (Blihar et al., 2020). Finally, PET scans of the brains of individuals with and without dissociative disorders show significant differences in the level of activity in both the sensory cortex and in areas of the brain previously found to be associated with integrated body schemes (Staniloiu, Vitcu, & Markowitsch, 2012). This sort of understanding is the first of many steps toward a complete understanding of the etiology of dissociation.

Personality Disorders

A **personality disorder** is a very rigid pattern of inner experience and outward behaviour. The pattern is seen in most of the person's interactions, continues for years, and differs markedly from the experiences and behaviours usually expected of people. Such disorders typically become recognizable in adolescence or early adulthood, although some seem to start during childhood (Sperry, 2016; Westen, Betan, & Defife, 2011). It has been estimated that as many as 9 to 13 percent of all adults may have a personality disorder (Volkert, Gablonski, & Rabung, 2018; Gawda & Czubak, 2017). Personality disorders are controversial, with many researchers and clinicians arguing that having a difficult personality does not necessarily constitute a disorder. Instead, they argue that personality problems might be better conceptualized as extremes on trait scales, such as the Big Five (Skodol, 2018; Trull & Durrett, 2005).

> **personality disorder** an inflexible pattern of inner experience and outward behaviour that causes distress or difficulty with daily functioning.

This debate became intense as the committee considering revisions to the Personality Disorders section of the *Diagnostic and Statistical Manual* discussed possible changes for the 5th edition of the DSM (Skodol, Morey, Bender, & Oldham, 2013). As we have seen in this chapter, the DSM generally addresses disorders categorically by defining criteria for diagnostic inclusion and then deciding, by applying defined criteria, whether an individual does or does not meet the criteria for diagnostic inclusion in a disorder category. In contrast with this categorical approach, we discussed in Chapter 12 how personality has been defined as a number of continuous dimensions along which individuals might be variably arrayed. In the DSM revision debate, some argued for a *personality* approach to personality disorders that would define personality disorders as patterns of extreme scores on a number of personality dimensions, perhaps related to but going beyond the Big 5 model (Sleep, Weiss, Lynam, & Miller, 2019; Watters & Bagby, 2018; Busch, Morey, & Hopwood, 2017; Wright, 2017). In the end, the categorical approach supports prevailed, arguing that a categorical approach was the one that clinical psychologists, who were

working with personality-disordered clients, were most familiar and comfortable with. As a result, the DSM-5 identifies 10 specific personality disorders that fall into three clusters: (1) odd/eccentric, (2) dramatic/erratic, and (3) anxious/inhibited. (see **Table 15.6**). However, the committee also agreed that a dimensional approach to personality disorders would be identified as a research priority and that the question will be reconsidered when it is time to start working on the 6th edition of the DSM (Skodol et al., 2013). Developments in this area will be very interesting to follow. Only two of the ten categorically defined Personality Disorders, the *antisocial* and *borderline personality disorders*, have been studied extensively, partly because they create so many problems for other people.

Antisocial Personality Disorder

Sometimes described as "psychopaths" or "sociopaths," people with **antisocial personality disorder** persistently disregard and violate others' rights (APA, 2013). Aside from substance-related disorders, this is the disorder most closely linked to adult criminal behaviour. Most people with antisocial personality disorder display some patterns of misbehaviour before the age of 15, including truancy, running away, physical cruelty to animals or people, and destroying property (DeLisi, Drury & Elbert, 2019; Whipp et al., 2019; Hodgins et al., 2018; Black, 2013).

> **antisocial personality disorder** a personality disorder characterized by extreme and callous disregard for the feelings and rights of others.

People with antisocial personality disorder lie repeatedly (Grant et al., 2019). Many cannot work consistently at a job; they are frequently absent and are likely to quit their jobs altogether. They are often careless with money and frequently fail to pay their debts. They are also often impulsive, taking action without thinking of the consequences (Hahn, Simons, & Hahn, 2016). Correspondingly, they may be irritable, aggressive, and quick to start fights.

Recklessness is another common trait: people with antisocial personality disorder have little regard for their own safety or for the safety of others, even their children. They are self-centred, and likely to have difficulty maintaining close relationships. They often have a knack for gaining personal profit at the expense of other people. The pain or damage they cause seldom concerns them; they appear to lack a moral conscience (Larsen, Jalava, & Griffiths, 2020). They think of their victims as weak and deserving of being conned or robbed.

TABLE 15.6

Clusters of Personality Disorders and Characteristic Features
Source: Morcos, N., & Morcos, R. (2016). Personality disorders: A measured response. *The Journal of Family Practice, 65*(2), 90–71.

Cluster/disorder	Features
Cluster A	
Paranoid	Excessive distrust and suspiciousness of others; pathologically jealous; interprets actions as demeaning, malevolent, threatening, or

	exploitative; ideas of reference (believes coincidences or innocuous events have strong personal significance)
Schizoid	Detachment from social interactions without a desire for close interpersonal relationships; restricted affect
Schizotypal	Eccentric beliefs without frank delusions; cognitive and perceptual disturbances; impaired social interactions
Cluster B	
Antisocial	Lack of empathy, with disregard for rights of others; deceitfulness, impulsivity, irresponsibility
Borderline	Unstable self-image; chronic feelings of emptiness; instability of interpersonal relationships; affective instability; self-harm behavior; hypersensitivity to rejection and fear of abandonment
Histrionic	Excessive attention-seeking behavior and emotionality; often excessively impressionistic and shallow
Narcissistic	Need for admiration; grandiosity in speech and behavior; lack of empathy for others, interpersonally exploitative; arrogant and haughty
Cluster C	
Dependent	Inability or extreme difficulty making own decisions; overly reliant on others; submissiveness; feelings of inadequacy; avoidance of confrontation
Avoidant	Feelings of inadequacy; hypersensitivity to rejection; social inhibition despite a desire to form close interpersonal relationships
Obsessive-compulsive	Preoccupation with details and rules; excessive organization; perfectionism, orderliness, miserliness; rigidity and stubbornness

Robert Hare of the University of British Columbia has developed a measure of psychopathy called the Psychopathy Checklist–Revised (PCL-R) (Hare, Neumann, & Mokros, 2018; Hare, 2013, 2003). Hare argues that psychopathy is a more extreme disorder than antisocial personality disorder, and argues that each should be considered separate from the other. The scale provides subscale scores on aggressive narcissism and socially deviant lifestyle. Scores on the scale correlate well with diagnoses of antisocial personality disorder, but the PCL-R is more specific. Hare's data indicate that while about 80 percent of individuals in Canadian prisons would meet the DSM criteria for antisocial personality disorder, only 20 percent would meet the PCL-R criteria for psychopathy (see photo). Further, Hare argues that the 20 percent identified by the PCL-R are responsible for 50 percent of the most serious crimes (Hare, 1993). (See Psychology Around Us 15.3.)

C_FOR/iStock/Getty Images

Psychopathy and crime **Half of all serious and repeat rapists and nearly half of all murderers meet the criteria for psychopathy on Robert Hare's PCL-R scale.**

Beyond Robert Hare's data, there are no general Canadian data available; however, American surveys indicate that as many as 2 to 3.5 percent of people in the United States meet the criteria for antisocial personality disorder (Volkert et al., 2018; Goldstein et al., 2016). It is likely that Canadian numbers are similar. The disorder is as much as four times more common among men than women.

Antisocial personality disordered individuals or perhaps sociopaths are often described as self-interested and driven to succeed and unconcerned about the feelings of others. Perhaps you have had a boss or heard about a corporate CEO (or president) who caused you to wonder if some sociopaths succeed in the business world. That thought has occurred to industrial organizational psychologists as well (Perry & Miller, 2017). What their research suggests fits well with what we have said above about antisocial personality disordered individuals: that the organizational situations where a sociopath might succeed are limited and leaders need much more that a personal desire to succeed. The Psychology@Work video on Leadership and Management: From Sociopaths to World Heroes looks at what else is required of leaders.

Video **PSYCHOLOGY@WORK**

Leadership and Management: From Sociopaths to World Heroes **This video looks at industrial/organizational psychology theory and research on leadership types. The video examines the meme that corporate CEOs might be sociopaths but indicates that this is not supported by data.**

15.3 Psychology Around Us

Not Criminally Responsible on Account of Mental Disorder

How does someone get declared "not criminally responsible on account of mental

disorder," and can people use this to "get away with murder"?

Is it possible for someone who was not clearly diagnosed as disordered before committing a violent act (a potential crime) to be found not responsible for the crime on account of a mental disorder? The concept of insanity, which is used in the U.S. legal system, is not a psychological one; its definition is legal. *Insanity* refers to a condition that excuses people from responsibility and protects them from punishment. From the legal point of view, a person cannot be held responsible for a crime if, at the time of the crime, the person lacked the capacity to distinguish right from wrong in order to obey the law. As Regina Schuller of York University and James Ogloff of Simon Fraser University point out, the Canadian legal outcome of "not criminally responsible on account of mental disorder" is not a diagnosis or even a psychological concept; it is simply a legal finding (Schuller & Ogloff, 2001). If a person is found "not criminally responsible by reason of mental disorder," he is neither convicted nor acquitted, and as such he is not formally sentenced. Instead, a court review board decides on the most appropriate arrangement, which could be an absolute discharge, a discharge with conditions (such as probation and/or treatment or medication), or detention in a hospital or institution.

On July 11, 2014, Bill C-14, the Not Criminally Responsible Reform Act, was passed in Canada. This legislation changed the Criminal Code of Canada regarding individuals found not criminally responsible due to a mental disorder. This bill is intended to enhance the rights of victims of violent crimes by persons found unfit to stand trial and to ensure public safety through tightened conditions for those under the authority of review boards. It also created a new "high risk accused" category. The effort to change the legislation was driven by the parents of Tim McLean, a young man decapitated while sleeping at the back of a Greyhound bus in 2008. The man charged with the murder, Vincent Li, had been previously diagnosed with schizophrenia. He believed God told him that his own life depended on his killing McLean. Li was found not criminally responsible on account of mental disorder. Those in favour of the legislation feel that it has not gone far enough to protect the public. Conversely, 11 Canadian mental health organizations (including the Canadian Psychological Association) have expressed strong disappointment with the legislation, pointing out that it is highly stigmatizing, perpetuates fear of those with mental illness, and diminishes the rights of individuals who are mentally ill (Crocker et al., 2015). It is important to recognize that justice is more than punishment and must be weighed against compassion and mercy.

What Causes Antisocial Personality Disorder?

Although the various models provide a range of explanations for antisocial personality disorder, none has managed to account for the broad range of symptoms found in the disorder. However, the behavioural and neuroscience models offer insights about particular symptoms.

Olgasea/Getty Images

Rewarding bad behaviour **Research suggests that some parents unintentionally teach antisocial behaviour by regularly rewarding a child's aggressive behaviour. For example, if a child defies a parent and the parent gives in to restore peace, the parent may be unintentionally teaching the child to be stubborn.**

According to a number of behavioural theorists, antisocial symptoms may be learned through modelling (Goulter, McMahon, Pasalich, & Dodge, 2019; Robinson, Azores-Gococo, Brennan, & Lilienfeld, 2016). As evidence, they point to the particularly high rate of antisocial personality disorder found among the parents of people with this disorder (though this could also reflect a genetic aspect of the disorder). Other behaviourists have suggested that some parents unintentionally teach antisocial behaviour by regularly rewarding a child's aggressive behaviour (Kazdin, 2018). When the child misbehaves or becomes violent in reaction to the parents' requests or orders, for example, the parents may give in to restore peace. Without meaning to, they may be teaching the child to be stubborn, and perhaps even violent (see photo).

Finally, a number of studies suggest that biological factors may play an important role in this disorder. Researchers have found, for example, that people with the disorder display lower serotonin activity than other individuals (Coccaro, Fanning, Phan, & Lee, 2016). Among other things, low serotonin activity has been linked to both impulsivity and aggression—key features of antisocial personality disorder (Duke et al., 2013). In addition, deficient functioning has been found in the frontal lobes of persons with this disorder (Reber & Tranel, 2019). Such a deficiency could help explain the poor planning, inferior judgments, and low empathy characteristic of this disorder (Glenn, Johnson, & Raine,

2013).

Still other research reveals that people with this disorder often experience less anxiety than other people, and so may lack a key ingredient for learning (Blair, Mitchell, & Blair, 2005). This would help explain why they have so much trouble learning from negative life experiences or tuning in to the emotional cues of others. Why should these individuals experience less anxiety than other people? It appears that many of them tend to respond to warnings or expectations of stress with low brain and bodily arousal (Davis-Siegel, Gottman, & Siegel, 2015). Perhaps because of the low arousal, the individuals easily tune out threatening or emotional situations, and so are unaffected by them. Recent brain scanning research is looking at the brains of Psychopaths and some of the differences found are described in Your Brain and Behavior 15.1.

15.1 Your Brain and Behaviour

Imagining the Psychopathic Brain

Psychopathy, which often fits under the category of antisocial personality disorder, and in the DSM-5 fits within the section on alternative model for personality disorders (Drislane et al., 2019), is a disorder that both fascinates and repels many of us. Psychopaths are often characterized by a distinct lack of feeling guilt, they often don't accept responsibility for their actions, and many view them as people who are willing to lie, manipulate, and charm to get what they want with very little or no empathy for the people they hurt. In a recent study comparing a group of psychopaths in the Netherlands to the U.S. one of the core features of psychopathy was a lack of empathy and a callousness toward others (Verschuere et al., 2017).

Approximately 1% of the population scores high on psychopathic traits. University of British Columbia professor emeritus Robert Hare has studied psychopathology for over 40 years. He is the creator of the Psychopathy Checklist and the Psychopathy Checklist Revised (PCL-R) that are used, in part, to predict the likelihood of psychopathic behaviour and to diagnose an individual with psychopathy (Hare, 2003; Ling & Raine, 2018). Dr. Hare's work formed the basis for our understanding of psychopathy from a behavioural perspective but what is happening in the brain's of these individuals? Dr. James Fallon at the University of California has spent his career imaging the brains of psychopaths and has found that the brain of a diagnosed psychopath is different from others in several key areas—especially the frontal lobes (Fallon, 2014)

While psychopathy is often associated with crime and deviance it is possible to be a diagnosed psychopath and live a very successful life without a history of illegal activity (Benning, Venebales & Hall, 2018). Interestingly, Dr. James Fallon is one of these individuals—he has the brain of a psychopath—similar to the very individuals he studies. This discovery was not intended, rather it happened by chance when his family was used as a control group for an Alzheimer's imaging study. One can only imagine Dr. Fallon's surprise at seeing his brain on a MRI scan looking indistinguishable from the brains of the psychopaths he studied. Individuals who score high in psychopathy but lead a successful life, such as Dr. Jim Fallon, are also now

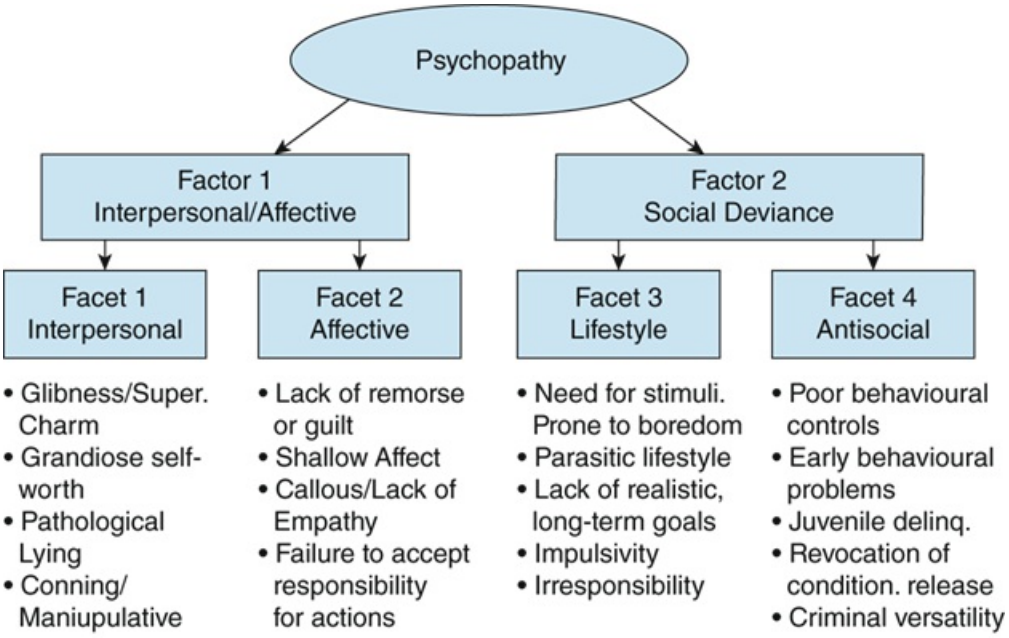
being studied and a recent brain imaging study has shown that there may be a higher density of grey matter—which indicates a higher density of neurons—in one area of the prefrontal cortex called the ventrolateral prefrontal cortex in these individuals. (Lasko et al., 2019)

Questions

What are the key behavioural characteristics of individuals who are diagnosed with psychopathy?

Which area of the brain has less activity during a cognitive task in individuals who score high on psychopathic traits?

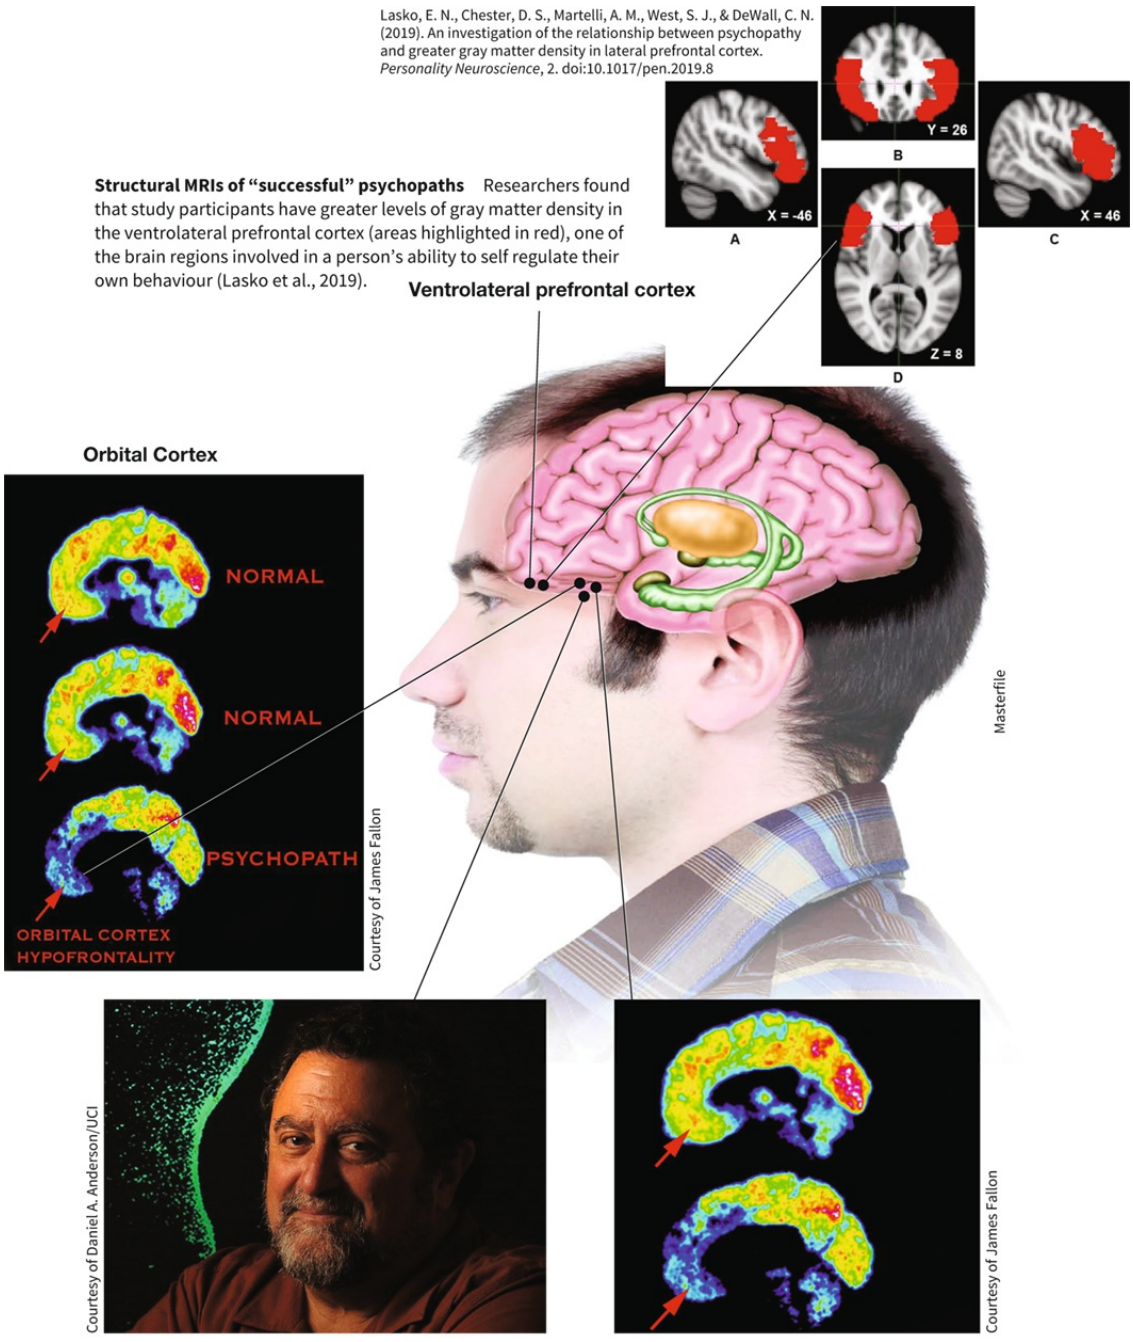
What areas of the brain have reduced connectivity between them when imagining another person in pain in individuals who score high on a checklist for psychopathy?



Scale structure of the PCL-R: Second edition Hare, R. D. Black, P.J., & Walsh, Z. (2003). The psychopathy checklist–Revised: Forensic Applications and Limitations. In R. P. Archer & E. M. A. Wheeler (Eds.) Forensic uses of Clinical Assessment Instruments. (pp. 230–265) New York, NY: Routledge.

The University of British Columbia

The psychopathology checklist by Dr. Robert Hare Dr. Hare at the University of British Columbia has been instrumental in describing psychopathic traits and has conducted forensic behavioural analysis of psychopaths. His work led to the development of the psychopathy checklist – revised (key elements shown here) which is still the primary questionnaire used by scientists to determine whether an individual has psychopathic tendencies (Hare, 2003).



Borderline Personality Disorder

People with **borderline personality disorder** display great instability, including major shifts in mood, an unstable self-image, and impulsivity. These characteristics combine to make their relationships very unstable as well (Paris, 2018: Gunderson, Weinberg, & Choi-Kain, 2013; APA, 2013). People diagnosed with this disorder move in and out of very

depressive, anxious, and irritable states that may last anywhere from a few hours to a few days or more. Their emotions seem to be always in conflict with the world around them. They are prone to bouts of extreme anger, which may at times result in physical aggression (Kolla, Meyer, Bagby, & Brijmohan, 2017; Martino et al., 2015; Leichsenring et al., 2011; Meyer, Ajchenbrenner, & Bowles, 2005; Koenigsberg et al., 2002).

> **borderline personality disorder** a personality disorder characterized by severe instability in emotions and self-concept and high levels of volatility.

Just as often, they direct their impulsive anger inward and inflict bodily harm on themselves—in the form of cutting or mutilating themselves (Goodman et al., 2017). Many try to hurt themselves as a way of dealing with their chronic feelings of emptiness, boredom, and identity confusion. Suicidal threats and actions are also common. Studies suggest that 75 percent of people with this disorder attempt suicide at least once in their lives; as many as 10 percent actually do commit suicide (Gunderson, 2011; Leichsenring et al., 2011).

People with borderline personality disorder frequently form intense, conflict-ridden relationships in which their feelings are not necessarily shared by the other person. They often violate the boundaries of a relationship. Thinking in *dichotomous* (black-and-white) terms, they quickly become furious when their expectations are not met. Yet they remain very attached to the relationships, paralyzed by a fear of being left alone. Sometimes they cut themselves or carry out other self-destructive acts to prevent partners from leaving (Berenson et al., 2011).

Around 2 percent of the general population is thought to suffer from this disorder (Paris, 2018; Volkert et al., 2018). Close to 75 percent of the patients who receive this diagnosis are women (Gunderson, 2011).

What Causes Borderline Personality Disorder?

Borderline personality disorder is not well understood. In recent years, however, a number of theorists have developed a *biosocial* theory to explain the disorder. According to this view, the disorder actually begins during childhood. It results from a combination of internal forces (for example, difficulty identifying and controlling one's arousal levels and emotions) and external forces (for example, an environment in which a child's emotions are punished or disregarded). If children have difficulties identifying and controlling their emotions, and if their parents further teach them to ignore their intense feelings, the children may never learn how to properly recognize and regulate their emotional arousal or how to tolerate emotional distress (Ahluwalia Cameron, Calderwood, & McMurphy, 2019; Chanen & Kaess, 2012; Arens et al., 2011).

Before You Go On

(Answers to Before You Go On may be found online in the Course Resources.)

What Do You Know?

18. What distinguishes a pain disorder associated with psychological factors from a conversion or somatization disorder?

19. List and describe three dissociative disorders.

20. Which disorder discussed in this section is most closely linked to adult criminal behaviour?

What Do You Think? • Analyze a character from a film you have seen or a book you have read that has one of the disorders described in this section. Is the information provided in the text consistent with what you know of the character?

Summary

Defining, Classifying, and Diagnosing Psychological Abnormality

LEARNING OBJECTIVE 1 Identify the common features of most definitions of abnormal functioning, and describe how psychological disorders are classified and diagnosed.

The study of psychological disorders is usually called *abnormal psychology*. Abnormal psychological functioning is a wide-ranging problem in this country.

Definitions of psychological disorders often include the "four Ds"—deviance, distress, dysfunction, and danger.

The Diagnostic and Statistical Manual of Mental Disorders (DSM) (current version DSM-5) is the leading classification system in North America.

Models of Abnormality

LEARNING OBJECTIVE 2 Describe the major models used by psychologists to explain abnormal functioning.

Clinicians use several major models to explain abnormal functioning, including the neuroscience, psychodynamic, cognitive-behavioural, humanistic-existential, socio-cultural, and developmental psychopathology models.

The neuroscience model views abnormal functioning as a result of malfunctions in brain structure or chemical activity. Malfunctions can be caused by injuries or other factors, including genetics or viruses.

Psychodynamic theorists view abnormal functioning as the result of unconscious conflicts that may have originated in our early development. Freud focused on fixations during the oral, anal, and phallic stages of development, while other theorists have focused on difficulties in ego development or our relationships with others.

Behavioural theorists propose that abnormal behaviours develop via the same processes as more adaptive behaviours: classical conditioning, operant conditioning, and modelling. Cognitive theorists believe that abnormal functioning can result from disordered thoughts, including basic irrational assumptions, specific upsetting thoughts, and illogical thinking processes.

Humanists suggest that people are vulnerable to psychological disorders when they develop inaccurate views of their worth or goals in life. Existentialist therapies focus on helping clients discover their personal freedom of choice and take responsibility for making choices.

According to the socio-cultural model, abnormal behaviour is best understood in light of the social, cultural, and family forces brought to bear on an individual. Important factors include social change, socio-economic class membership, cultural background, social networks, and family systems.

Developmental psychopathology theorists are interested in how psychological disorders evolve, based on both genetics and early childhood experiences, and on how those early patterns affect people's functioning as they move through later life stages.

Mood Disorders

LEARNING OBJECTIVE 3 Describe and differentiate major depressive disorder and bipolar disorder.

The key features in mood disorders are *depression*—a low, sad state—and *mania*—a state of breathless euphoria. Most people with a mood disorder suffer only from depression.

People with *major depressive disorder* suffer a variety of symptoms, including feelings of sadness and lack of interest, low levels of activity and productivity, negative views of themselves and their lives, and physical ailments.

Today's leading explanations for major depressive disorder point to neuroscientific, psychological, or socio-cultural factors. Many theorists believe that the various explanations should be combined.

People with *bipolar disorder* experience not only the lows of depression, but also the highs of mania. In the manic state, they want constant excitement. They tend to show poor judgment and planning, hold inflated opinions of themselves, and show a great deal of energy.

Although genes and biological factors appear to play key roles in the development of bipolar disorder, there is growing evidence that stress and certain kinds of environmental events also must occur in order for episodes to unfold.

Anxiety Disorders

LEARNING OBJECTIVE 4 Describe the various types of anxiety disorders, and explain some causes of these disorders.

As a group, anxiety disorders are the most common mental disorders in North America. Often, people with one type of anxiety disorder have another type as well.

People with *generalized anxiety disorder* experience persistent feelings of worry and anxiety. Some cognitive theorists suggest that this disorder arises in people who hold certain dysfunctional or irrational assumptions, while others focus on the individual's intolerance of uncertainty. An important neuroscience explanation focuses on gamma-aminobutyric acid, a neurotransmitter involved in fear reactions.

People with *social anxiety disorder* display severe, persistent, and irrational fears of social or performance situations. Some socio-cultural factors appear to be involved.

People with *phobias* have a persistent and irrational fear of a specific object, activity, or situation. Behavioural principles, including classical conditioning and modelling, provide the leading explanations for specific phobias.

People with *panic disorder* have recurrent attacks of terror. These *panic attacks* are sometimes accompanied by *agoraphobia*—a fear of venturing into public places. A neuroscience-cognitive explanation of the disorder focuses on physical sensations produced by malfunctioning brain circuitry, which are then misinterpreted.

People with *obsessive-compulsive disorder* feel overrun by recurrent thoughts that cause anxiety (obsessions) and by the need to perform repetitive actions to reduce this anxiety (compulsions). While cognitive-behavioural theorists focus on the role of learning in these behaviours, neuroscientists focus on abnormally low levels of serotonin or abnormal functioning in specific brain regions.

People with *posttraumatic stress disorder (PTSD)* are tormented by fear and related symptoms well after a horrifying event has ended. Although extraordinary trauma causes the disorder, not everyone who experiences such trauma develops PTSD. Differences in biological processes, personalities, childhood experiences, social support systems, and cultural backgrounds make people more or less likely to respond to trauma by developing the disorder.

Schizophrenia

LEARNING OBJECTIVE 5 Describe the features of schizophrenia and some theories of what causes it.

Schizophrenia is a disorder in which people deteriorate into a world of unusual perceptions, odd thoughts, disturbed emotions, and motor abnormalities. These people experience *psychosis*, a loss of contact with reality.

Positive symptoms of schizophrenia are "pathological excesses" in behaviour. They include delusions, disorganized thinking and speech, hallucinations, and inappropriate affect.

Negative symptoms, or "pathological deficits," include poverty of speech, flat affect, loss of volition, and social withdrawal.

People with schizophrenia also sometimes experience unusual psychomotor symptoms, which in their most extreme form are collectively called *catatonia*.

Many theorists believe that people inherit a genetic predisposition to schizophrenia. Two kinds of brain abnormalities might be inherited—biochemical abnormalities and abnormal brain structure.

Although neuroscience explanations of schizophrenia have received by far the most research support, psychological and socio-cultural factors may help to bring about schizophrenia in people with a biological predisposition to develop it.

Other Disorders

LEARNING OBJECTIVE 6 Discuss the features and possible causes of somatic symptom and related disorders, dissociative, and personality disorders.

Somatic symptom and related disorders include five diagnoses: somatic symptom disorder, illness anxiety disorder, conversion disorder (functional neurological symptom disorder), psychological factors affecting other medical conditions, and factitious disorder.

Somatic symptom and related disorders are thought to result from classical conditioning, modelling, or misinterpretation of bodily cues, similar to anxiety disorders. Cognitive theorists suggest that people with one of these types of disorders are extremely sensitive to bodily cues and come to misinterpret them.

Changes in memory that lack a physical cause are called *dissociative disorders*. DSM-5 includes three major dissociative disorders: dissociative amnesia, depersonalization/derealization disorder, and dissociative identity disorder. In *dissociative amnesia*, people are unable to recall important information about their lives. In *depersonalization/derealization disorder*, stress alters perceptions, detaching the self from the body. In *dissociative fugue*, people not only forget their identities and their past lives, but also flee to a different location. In *dissociative identity disorder*, people develop two or more distinct personalities.

Psychodynamic theorists believe that dissociative disorders are caused by repression, the most basic ego defence mechanism, but this view has not received strong research support.

People with *antisocial personality disorder* persistently disregard and violate others' rights. Because of their potentially negative behaviour, such as lying, impulsiveness, and recklessness, they are frequently found in prison. According to behavioural theorists, this disorder can be learned through various means. Neuroscience explanations focus on brain factors, such as low serotonin levels, deficient frontal lobe functioning, and low arousal in response to warnings.

People with *borderline personality disorder* display great instability, including major shifts in mood, an unstable self-image, and impulsivity. This disorder is not well understood, but a recent biosocial theory proposes that it results from a combination of internal and external forces.

Self-Study Questions

Multiple Choice

1. The medical model

a. encourages a search for patterns of symptoms.

b. is heavily dependent on social norms and values.

c. is unconcerned with underlying etiology.

d. disassociates physical illness and "madness."

2. Behaviour, thoughts, and emotions are considered abnormal when they differ from a society's ideas about proper functioning. Which of the following "four Ds" does this statement represent?

a. deviance

b. distress

c. dysfunction

d. danger

3. Which of the following statements best reflects the psychodynamic approach to defining abnormal behaviour?

a. It is learned through the observation of societal norms.

b. It is observed in other individuals we identify with.

c. It results from maladaptive thinking patterns.

d. It results from unconscious attempts to solve conflicts.

4. Humanistic and existential theories have in common a belief that

a. people are naturally inclined to live constructively.

b. people have complete freedom to give meaning to their lives or to run away from that responsibility.

c. people must have high levels of self-awareness to live meaningful, well-adjusted lives.

d. the therapist is an expert who can provide answers for the client.

5. Beck's cognitive triad includes negative thoughts about all of the following except

a. one's experience.

b. oneself.

c. others.

d. the future.

6. People with major depressive disorder often have low levels of the neurotransmitters

a. acetylcholine and dopamine.

b. dopamine and serotonin.

c. GABA and acetylcholine.

d. norepinephrine and serotonin.

7. Albert Ellis believed that abnormal patterns of functioning are caused primarily by

a. faulty conditioning.

b. imitating maladaptive models.

c. irrational assumptions.

d. learned helplessness.

8. The brain circuit that produces anxiety in a person includes all of the following brain structures except the

a. amygdala.

b. anterior cingulate.

c. hippocampus.

d. prefrontal cortex.

9. Which of the following is an example of a negative symptom of schizophrenia?

a. being unable to show any emotion

b. believing that others can read one's thoughts

c. hearing voices that are not real

d. using rapid, incoherent speech

10. A man who forgets the details of his life and identity and sets up a new life in a different location is likely experiencing dissociative

a. amnesia.

b. fugue.

c. identity disorder.

d. somatization.

Fill-in-the-Blank

1. A person whose thoughts or behaviour are far outside the norm for the time and place in which he or she lives is demonstrating the _____ aspect of psychological abnormality.

2. A client who is diagnosed with both major depressive disorder and generalized anxiety

disorder is said to be experiencing _____.

3. The notion of modelling, first studied by _____, helps explain why people whose parents had psychological disturbances often have psychological disturbances themselves.

4. The tendency for children who start out in the same situation to end up at very different places, psychologically speaking, is called _____.

5. Persistent Depressive Disorder (dysthymia) is to major depressive disorder as _____ disorder is to bipolar disorder.

6. The most common category of psychological disturbance in Canada is _____ disorders.

7. Posttraumatic stress disorder and _____ disorder have similar symptoms, but those symptoms arise at different points after the traumatic event and linger for different amounts of time.

8. In schizophrenia, _____ symptoms involve the addition of inappropriate behaviour, such as hallucinations or delusions.

9. The concordance rate for schizophrenia is much higher in _____ twins than in _____ twins, suggesting that genes play an important role in the development of the disorder.

10. Research shows that people with antisocial personality disorder often have deficient functioning in the _____ lobes of the brain.

CHAPTER 16
Treatment of Psychological Disorders

Steve Debenport/Getty Images

CHAPTER OUTLINE

Treatment in Today's World

LEARNING OBJECTIVE 1 Explain who receives treatment for psychological problems today, how they enter treatment, and what general features characterize different types of treatment.

Biological Treatments

LEARNING OBJECTIVE 2 Describe the major biological treatments for psychological disorders.

Psychodynamic Therapies

LEARNING OBJECTIVE 3 Describe the psychodynamic treatments for psychological disorders.

Behavioural Therapies

LEARNING OBJECTIVE 4 Describe the behavioural treatments for psychological disorders.

Cognitive-Behavioural Therapies

LEARNING OBJECTIVE 5 Describe cognitive-behavioural therapies for psychological disorders.

Humanistic and Existential Therapies

LEARNING OBJECTIVE 6 Describe the humanistic and existential therapies for psychological disorders.

Formats of Therapy

LEARNING OBJECTIVE 7 Describe commonly used formats of therapy.

Does Therapy Work?

LEARNING OBJECTIVE 8 Summarize research on the effectiveness of therapy.

Some Final Thoughts About the Field of Psychology

February: *She cannot leave the house; Romy knows that for a fact. Home is the only place where she feels safe—safe from humiliation, danger, and rejection. If she were to go to work, her co-workers would somehow reveal their contempt for her. A pointed remark, a quizzical look—that's all it would take for her to know how much they disliked her. If she were to go shopping at the store, before long everyone would be staring at her. Surely others would see her anxious mood and thoughts; she wouldn't be able to hide them. She didn't even dare to walk around her neighbourhood—her heart would probably start racing again, bringing her to her knees and leaving her breathless, incoherent, and unable to get home. No, she's much better off staying in her room, trying to get through another evening of her lonely existence. Thank goodness for social media. Were it not for her ability to connect through the Internet, Romy knew she would be completely alone.*

July: *Romy's busy social life revolves around a small group of friends: Anna, Charlotte, and Joseph from the office, where Romy was recently promoted to director of customer relations, and Kirby and Josh, her weekend hiking friends. Her friends meet for dinner every week at someone's house, and they chat about life, politics, and their jobs. Particularly special in Romy's life is Quinn. They go to movies, restaurants, and concerts together. Quinn thinks Romy is terrific, and Romy finds herself beaming whenever she thinks about Quinn or whenever Quinn is near. Romy looks forward to work each day and to her interactions with colleagues and customers. She's reconnected with family and old friends and is more fully enjoying her life than ever before.*

Romy's thoughts, feelings, and behaviour interfered with all aspects of her life in February, yet most of her symptoms had disappeared by July. Many factors may have contributed to Romy's improvement—advice from friends and family members, a new job or vacation, perhaps a big change in her diet or exercise regimen. Any or all of these things may have been useful, but they could not be considered **treatment**, or **therapy**. Those terms are usually reserved for specific, systematic procedures designed to change abnormal behaviour into more normal behaviour (see photo). According to clinical theorist Jerome Frank, all forms of therapy have three essential features:

A *sufferer* who seeks relief from the healer.

A trained, socially accepted *healer*, whose expertise is accepted by the sufferer and his social group.

A *series of contacts* between the healer and the sufferer, through which the healer tries to produce certain changes in the sufferer's emotional state, attitudes, and behaviour. The healing process may be brought about primarily by **psychotherapy**—in Frank's words, "by words, acts, and rituals in which sufferer, healer, and—if there is one—group participate jointly." Or it may be accomplished through **biological therapy**, consisting of "physical and chemical procedures" (Frank, 1973, pp. 2–3).

treatment or **therapy** systematic procedures designed to change abnormal behaviour into more normal behaviour.

psychotherapy a treatment system in which a client and therapist use words and acts to overcome the client's psychological difficulties.

biological therapy the use of physical and chemical procedures to help people overcome psychological difficulties.

BEW Authors/AGE Fotostock

Getting help **Therapy is a systematic procedure to help people deal with the pathology, adjustment issues, or day-to-day problems that are negatively affecting their lives.**

Healers are called *clinicians*, *clinical practitioners*, or *therapists*. You read about the work of *clinical researchers* in Chapter 15. As you saw, they systematically gather information so that they can better describe, explain, and predict psychological disorders. The knowledge that they acquire is then used by clinicians, whose role is to detect, assess, and treat people with psychological disorders. The important role Indigenous Elders can play as part of a clinical team is shown in Indigenous Experiences 16.1.

Despite Frank's (1973) straightforward definition, clinical treatment is surrounded by conflict and confusion. In fact, Carl Rogers has been cited as saying that "therapists are not in agreement as to their goals or aims. . . . They are not in agreement as to what constitutes a successful outcome of their work. They cannot agree as to what constitutes a failure. It seems as though the field is completely chaotic and divided" (Thorne & Sanders, 2013).

Some clinicians view abnormality as an illness and so consider therapy a procedure that helps cure the illness. Others see abnormality as a problem in living and therapists as teachers of more functional behaviour and thought. Clinicians even differ on what to call the person who receives therapy. Those who see abnormality as an illness speak of the "patient," while those who view it as a problem in living refer to the "client." Because both terms are common, this chapter will use them interchangeably.

16.1 Indigenous Experiences

Including Elders in Mental Health Care

Indigenous people in Canada experience significantly distorted rates of mental illness and suicidality, which are legacies of colonization, oppression, and systemic racism. Indigenous people frequently experience discrimination and indifference from health care providers, leading them to develop limited trust in the health care system for mental health and other issues (Browne et al., 2016). However, evidence suggests that Elders can play a transformative role in the mental health of Indigenous people in traditional settings (TRC, 2015).

One of the 94 calls to action of the Truth and Reconciliation Commission's report is to include Elders in the treatment of Indigenous patients in the wider health care system. Elders are "those who have shown wisdom and leadership in cultural, historical, and spiritual matters within their communities, and might not necessarily be old. Elders represent an essential connection with the past; they are keepers of the community knowledge and supporters of its collective spirit" (Hadjipavlou et al., 2018, p. E609).

George Hadjipavlou, at the University of British Columbia, and colleagues (2018) assessed the impact of a partnership program involving Indigenous Elders who provided direct patient care to Indigenous patients attending an inner-city primary care clinic. Patients had mental health and substance disorders as well as chronic pain or stigmatizing health conditions, such as HIV. Five overarching themes from participants representing 20 different First Nations were obtained:

> **Theme 1:** *Finding a place of healing after a prolonged period of seeking and desperation*: Participants found Elders to be non-judgmental, genuine, accepting, and safe. One said, "I feel that these people understand me, and they have a connection to … the trails I went down when I thought I was so alone, so ostracized and even abandoned." (p. E610)
>
> **Theme 2:** *Strengthening cultural identity and belonging*: Participants reported improvements in self-esteem and self-confidence because of Elders increasing the patients' sense of cultural identity. One said, "And meeting with [the Elders] has given me this: 'it's OK to be Native'…Like I know that, but they reinforced that … it's given me more confidence. It gave me a little bit more self-esteem. It's healed me a bit." (p. E611)
>
> **Theme 3**: *Developing trust and "opening up"*: In contrast to their mistrust of the health care system, participants reported trusting the Elders and "opening up" to engage meaningfully with their health and culture. One said, "[The Elder] really helped me through talking, just sitting and talking and just brought my spirit back." (p. E612)
>
> **Theme 4**: *Coping with losses*: Most participants had suffered multiple significant losses in their families and communities and reported that the Elders offered them ways to bear their grief. One said, "It cleared up a lot of things about growing up and life and losing my grandparents and losing my mom …and not just going nuts and committing suicide…I loved it, just talking with her." (p. E612)
>
> **Theme 5**: *Engaging in ceremony and spiritual dimensions of care as a resource for hope*: Participants reported that Elders provided spiritual guidance that they

could not access from traditional health care providers. These spiritual teachings helped them to restore hope. One said, "…this Elder program has changed – like changed my life. I'm willing to live now…I've never experienced anything as positive when it comes to my spiritual, emotional well-being. That having this kind of [Elder] support is life changing." (p. E613)

THE CANADIAN PRESS/Darryl Dyck

The role of Elders Elders are selected because they display highly valued qualities such as leadership, wisdom, and compassion, as well as demonstrate a deep understanding of their history, traditional teachings, and healing practices. Here, Elder Annie Johnson joins other Elders to lead a march in Vancouver, BC, to honour missing Indigenous women and girls.

The results of the Hadjipavlou et al. (2018) study demonstrate the need for including Elders in partnership with mainstream health care services for Indigenous people.

Critical Thinking Questions

Would you consider an Elder to be a clinician? Why or why not?

Based on the descriptions presented in the overarching themes, would you say that the Elders described, view abnormality as an illness or as a problem of living? Why?

Despite their differences, most clinicians do agree that large numbers of people need therapy of one kind or another. Later you will encounter empirical support indicating that therapy is indeed often beneficial to those who need it.

Treatment in Today's World

LEARNING OBJECTIVE 1

Explain who receives treatment for psychological problems today, how they enter treatment, and what general features characterize different types of treatment.

A Canadian Mental Health Association (CMHA, 2015) poll conducted by Nanos Research on mental health funding found that 94 percent of Canadians felt that as much or more government funding should be directed to mental health as physical health. The CMHA also cited a 2012 Statistics Canada survey that indicated that 1 in 6 Canadians over the age of 15 had a need for mental health services. The Mental Health Commission of Canada (2012) has also called for increased spending on mental issues. The number and variety of problems for which treatments are available have increased during the past century or more. When Freud and his colleagues first began conducting therapy during the late nineteenth and early twentieth centuries, most of their patients suffered from anxiety or depression. People with schizophrenia and other more severe disorders were considered poor prospects for therapy, and treatment for them was confined to custodial care in institutions (Levin, Hennessy, & Petrila, 2010).

Although a Statistics Canada report (2012) indicated that 76.9 percent of Canadians over 15 years of age perceived themselves to be "flourishing" with "complete" mental health, 10 percent of Canadians in that age group (2.8 million) reported symptoms associated with a mental disorder (major depressive episode, bipolar disorder, generalized anxiety disorder) or a substance use disorder in the past year (Statistics Canada, 2012). These disorders, including anxiety and depression, still dominate the therapy picture, as more than three-quarters of Canadians diagnosed with a mental illness each year suffer from one or the other of these two disorder types (Langlois et al., 2011). However, people with other kinds of disorders also receive therapy (NIDA, 2011; CDC, 2010; SAMHSA, 2010). People with schizophrenia and people with substance-related disorders, for example, make up a large percentage of the clients in therapy today. Moreover, large numbers of people with milder psychological problems, sometimes called "problems in living," are also in therapy. Surveys suggest that non-disordered reasons for entering therapy largely include problems with marriage, family, job, peer, school, or community relationships (Mojtabai et al., 2011).

Among other facts on its *Fast Facts about Mental Illness* page (www.cmha.ca/media/fast-facts-about-mental-illness), the Canadian Mental Health Association (2014b) states the following: 20 percent of Canadians will experience a mental illness in their lifetime; 8 percent will experience a major depression; 1 percent will experience bipolar disorder; and 5 percent of households will experience mild to severe anxiety. Importantly, the Canadian Mental Health Association also states that although mental illness can be treated effectively, many people do not seek treatment because of the stigma associated with mental illness.

Who Seeks Treatment?

Other characteristics of clients have also changed over the years. Until the middle of the twentieth century, therapy was primarily a privilege of the wealthy, largely because of the high fees that out-patients were required to pay. After all, Freud's fee for one session of therapy in 1925 was $25 (eqivalent to $371 in today's dollars). The current cost of private out-patient therapy varies by service and location. Provincial psychologists' regulatory groups (e.g., the Ontario College of Psychologists) set the hourly rate for psychological therapy. The hourly rate in Canada typically ranges from $125 to $225. However, with the

expansion of third-party coverage (such as Blue Cross) and the emergence of publicly supported community mental health centres, people at all socio-economic levels can now theoretically receive both out-patient and in-patient therapy at more affordable rates. However, in spite of moderate increases in support, timely, affordable psychological therapy continues to be out of reach for many individuals. There continue to be long wait times for access to publicly funded psychologists and high costs for quick access to private psychologists.

Women used to outnumber men in therapy by four to one, partly because they were less reluctant than men to seek help. Lately, however, our society's attitudes and sex-role expectations have been changing. Men are more willing to enter therapy than before (Oliffe et al., 2016; Strokoff, Halford, & Owen, 2016; Clement et al., 2015). In fact, more than one-third of today's therapy patients are male (NIDA, 2011; CDC, 2010). As you will see later in this chapter, however, members of ethnic minority groups tend to seek treatment for their psychological problems less often than members of the majority culture (Clement et al., 2015; Brown et al., 2014; Cheng, Kwan, & Sevig, 2013).

Entering and Receiving Treatment

People enter therapy in various ways. Many decide on their own to consult a therapist. Others may do so on the advice of a friend, family member, minister, physician, or other professional with whom they have discussed their difficulties. Still others are forced into treatment. Parents, spouses, teachers, and employers may virtually order people to seek treatment if they are causing disruptions or are in obvious distress; or judges may formally pronounce people mentally disturbed and dangerous and commit them to a mental hospital for treatment.

fizkes/Shutterstock.com

The stigma of seeking therapy **Many people don't seek therapy because there is a social stigma associated with it. Instead, they suffer in silence. The truth is that therapy can benefit anyone, and it is not a weakness to seek help.**

In most cases, the decision to seek therapy is not easy. Stigma is a barrier to seeking treatment for many (Clement et al., 2015). Extensive studies indicate that most individuals are aware of their problems well before they look for help (see photo). Many wait more

than two years after they first become aware that they have a problem. And it is estimated that at least half of the people with psychological disorders never seek treatment (Ndumele & Trivedi, 2011).

The under-use of therapy has a long history. Back in the 1970s, for example, a labour union in the United States, the United Auto Workers, negotiated a contract in which management agreed to pay the entire cost of both in-patient and out-patient mental health services for a million union members. Yet, after three years, only 1 percent of eligible workers had used the benefit (Brown, 1976). Apparently they and their referral agents (shop foremen, clergy, and others) were either unaware of the benefit, ignorant of what therapy could do for them, unlikely to think about personal problems in mental health terms, or worried about the stigma that psychological problems might bring in their social set.

Heather Stuart of Queens University, the first Bell Mental Health and Anti-Stigma Research Chair (from 2013–2014), and currently the senior consultant to the Mental Health Commission of Canada's Opening Minds program, has reviewed the history of efforts within Canada to reduce the stigma associated with acknowledging and obtaining treatment for mental illness (Stuart et al., 2014). As far back as the 1950s, efforts were underway to reduce the stigma associated with mental illness and to help Canadians move toward an understanding that many mental illnesses can be treated, and that most can be treated outside of hospital settings. For example, as efforts were underway to reduce the number of mental patients treated in hospitals, there was initial resistance from the public based on unfounded fears regarding public safety if mentally ill people were treated on an out-patient basis. Since that time, there has been a significant reduction in the stigma associated with mental illness (Stuart, 2012). However, perceptions of stigma continue to play a role in people's decisions about whether or not to acknowledge their mental issues and whether or not to seek treatment.

Conducting Treatment: Who, Where, and How

A variety of professionals conduct therapy today. Most are psychologists, psychiatrists, counsellors, and psychiatric social workers. Whatever their profession, these therapists generally see the same kinds of clients. That is, the majority of their clients are people with anxiety, depression, or relationship problems. However, although psychiatrists treat clients with depression, anxiety, and relationship issues, they see a much larger number of patients with schizophrenia, bipolar disorders, and other severe disorders than do psychologists, counsellors, or social workers. The providers of mental health services are concentrated in urban areas across Canada. As a result, there is a shortage of practitioners available to serve the needs of the many people who live in rural areas (Beaulieu & Schmelefske, 2016; Dyck & Hardy, 2013; Sealy, 2012). Even in the larger centres, some kinds of services are easier to access (e.g., medications through hospital psychiatric or emergency wards) than others (e.g., counselling, therapy, and support).

Therapy takes place in a wide variety of settings, from public institutions to schools to private offices. Most clients, even those who are severely disturbed, are treated as out-patients. They live in the community and make regular visits to the therapist's office or hospital/clinic. Most of the people who receive in-patient treatment, whether in the psychiatric wards of general hospitals or in psychiatric hospitals, have severe psychological problems (Craig & Power, 2010). As already discussed, the Canadian health care system

promises to ensure mental health services and necessary treatments to all who need them, either through hospital facilities or out-patient clinics. However, inadequate funding means that many individuals with mental health needs go untreated (Johansen & Sanmartin, 2011).

Republic Pictures/Stringer/Archive Photos/Getty Images

The "crazy house" For many, the perception of psychiatric care continues to be something like the treatment received by the patients portrayed in the well-known movie *One Flew Over the Cuckoo's Nest* (Beachum, 2010). However, the reality is that laws and policies protect Canadians hospitalized with mental illness.

Guidelines for admitting individuals to psychiatric facilities, either voluntarily or involuntarily, are provided in the Canadian Mental Health Act. This act includes information on the conditions under which people can be admitted and detained in hospital against their will, and also outlines the rights of patients in psychiatric facilities (see photo; Lewis, 2013).

Clinicians have become increasingly concerned about the negative effects of long-term institutionalization. Thus, beginning in the 1960s, clinicians lobbied for a policy of *deinstitutionalization* (Davison et al., 2010). In 2006, Patricia Sealy and her colleague, Paul Whitehead at the University of Western Ontario, examined the impact of 40 years of deinstituionalization, reporting that the policy had variable impacts on mental health provinicially. Their results suggested that the earlier that provinces implemented deinstituionalization, the lower the levels of social inequities for access. (Sealy, 2012). The number of psychiatric beds per 1,000 people went from four in 1964 to one in 1975, and the total number of psychiatric beds dropped from 54,801 in 1975 to 20,301 in 1981 (see also Goldner, Bilsker, & Jenkins, 2016; Sealy, 2012).

Hospitalization today usually lasts weeks instead of months or years. When people develop severe psychological disorders, therapists now try to treat them first as out-patients, usually with medications along with other forms of therapy. If this strategy proves ineffective, the patient may be admitted to a hospital for a short period (usually 24 to 72 hours) so that the condition can be monitored, diagnosed, and stabilized. As soon as

hospitalization has served the purpose of stabilization, the patient is returned to the community.

In theory, this may seem a reasonable treatment plan for people with severe psychological disorders. However, as you will see later, community treatment facilities have been so underfunded and understaffed over the years that they have not been able to meet the treatment needs of the majority of severely impaired people. Indeed, many people with severe psychological disorders are currently condemned to an endless cycle of hospital discharges and readmissions, and are often homeless (Adair et al., 2016; Sealy, 2012). According to the Canadian Institute for Health Information (2012), 14.7 percent of all hospitalizations in Canada involve a mental health diagnosis, with one-third of these patients being readmitted to hospital within one year of release following treatment of a mental illness. Moreover, Sealy & Whitehead's 2006 data indicated that most people with the highest levels of distress continued to be unable to access mental health services at all (Sealy, 2012).

Whether treated as an out-patient or in hospital, not all patients have similar experiences. By some estimates, there are more than 400 forms of therapy in the clinical field today, each practised by clinicians who believe that their chosen methodology is highly effective (Consoli, Beutler, & Bongar, 2017). Typically, therapists use principles and techniques that they have been trained in and that are consistent with the theories of psychological dysfunction they have been taught (Karpiak, Norcross, & Wedding, 2016).

In Chapter 15, you read about today's leading theories for explaining psychological disorders. Proponents of those explanations have proposed corresponding treatment approaches, and clinical practitioners have put those approaches into action as they work with clients. Carl Rogers's humanistic theory, for example, identifies self-awareness and self-actualization as fundamental to good mental health. Correspondingly, therapists who follow his client-centred treatment approach listen to and empathize with clients, expecting that such techniques will help the clients become better aware of themselves and more able to actualize their special human potential (Nienhuis, et al., 2016).

The following sections in the chapter focus on biological, psychodynamic, behavioural, cognitive-behavioural, and humanistic-existential therapies (see **Table 16.1**). Recall from our chapter opener, though, that all these forms of therapy have three essential features: a sufferer who seeks relief, a trained healer, and a series of contacts between the two in which the healer tries to bring about changes in the sufferer's emotional state, attitudes, and behaviour.

TABLE 16.1

Comparison of Treatments for Psychological Disorders

	Goals of Therapy	Therapy Techniques	Strengths	Weaknesses
Biological Approaches	Improve structural or biochemical	Psychotropic drugs; electroconvulsive	Often effective for people	Side effects Not always effective

	functioning; relieve symptoms	therapy (ECT); psychosurgery	whose problems don't respond to other treatments	May neglect non-biological problems of clients
Psychodynamic Approaches	Discover source of conflicts and resolve them	Free association; therapist analysis of resistance, transference, and dreams; catharsis; and working through problems	Offered first major alternative to biological treatments Sees abnormal functioning as rooted in same processes as normal functioning Model for many other psychological treatments	Depends on therapist's subjective interpretation
Behavioural Approaches	Learn more functional behaviours	Desensitization; aversion therapy; operant conditioning, including token economies; therapist modelling, including social-skills training	Research often supports effectiveness of treatments	Effects of treatment may not always last long after treatment stops May neglect unobservable cognitive processes
Cognitive-Behavioural Approaches	Change harmful thinking patterns to more useful ones	Rational-emotive therapy; cognitive therapy; cognitive-behavioural techniques	Considerable research support for its application to several disorders	Dysfunctional thinking may result from, not cause, abnormal functioning

Humanistic and Existential Approaches	Provide support for honest self-appraisal, self-acceptance, and self-actualization	Client-centred and Gestalt therapy techniques; existential therapy	Recognize positive human goals Recognize distinctly human values and needs	Unsupportive and limited research to test effectiveness

Before You Go On

(Answers to Before You Go On may be found online in the Course Resources.)

What Do You Know?

1. What trends have changed who tends to receive treatment for psychological disorders?

2. How does in-patient therapy differ from out-patient therapy?

3. What are the three key features common to all forms of therapy?

What Do You Think? • Why do you suppose people tend to wait so long before seeking help for a psychological problem? If you were experiencing some sort of psychological difficulty—say, depression—how do you think you would arrive at the decision to get treatment?

Biological Treatments

LEARNING OBJECTIVE 2

Describe the major biological treatments for psychological disorders.

Biological therapies use chemical and physical methods to help people overcome their psychological problems. The practitioners who apply such approaches are usually *psychiatrists*, therapists whose training includes medical school. The three principal kinds of brain biological interventions are *drug therapy*, *electroconvulsive therapy*, and *psychosurgery*. Drug therapy is by far the most common of the biological approaches.

Drug Therapy

Many types of disorders are treated with drug therapies or medical or surgical procedures that act directly on the central nervous system. We will first address the use of **psychotropic drugs**; drugs that act primarily on the brain and, in many cases, significantly reduce the symptoms of psychological disorders (Julien, Advokat, & Comaty, 2011) (see

photo). We will then discuss other medical interventions for treating psychological disorders.

psychotropic drugs medications that act primarily on the brain.

Since the 1950s, discoveries in *psychopharmacology* (a branch of study that focuses on the action of drugs on the mind and behaviour) have transformed the treatment of psychological disorders. Such drugs are now widely used, either as the first-line treatment for a disorder or in conjunction with psychotherapy or other interventions (Hammersley, 2016).

As you can see in **Table 16.2**, four major psychotropic drug groups are used in therapy: antipsychotic drugs, antidepressant drugs, mood stabilizers, and antianxiety drugs. **Antipsychotic drugs** help reduce the confusion, hallucinations, and delusions of *psychotic disorders*, the disorders (such as schizophrenia) marked by a loss of contact with reality, as well as the severe mood disorders accompanied by delusions. **Antidepressant drugs** help improve the mood of people who are depressed. **Mood stabilizing drugs** help level the moods of those with a bipolar disorder, the condition marked by mood swings from mania to depression. **Antianxiety drugs**, also called *minor tranquilizers* or *anxiolytics*, help reduce tension and anxiety. Let's look at each of these drug groups in turn.

antipsychotic drugs psychotropic drugs that help correct grossly confused or distorted thinking.

antidepressant drugs psychotropic drugs that lift the mood of depressed people.

mood stabilizing drugs psychotropic drugs that help stabilize the moods of people suffering from bipolar disorder.

antianxiety drugs psychotropic drugs that reduce tension and anxiety.

Stephen Kelly - PA Images/Getty Images

Psychopharmacology Drugs are now widely used to treat psychological disorders, often in conjunction with other forms of therapy.

Antipsychotic Drugs

Beginning in about 1955, individuals suffering from schizophrenia and other disorders were frequently prescribed antipsychotic drugs. The use of these drugs and the reduction of symptoms had the effect of radically reducing the number of mentally ill involuntarily hospitalized and institutionalized patients in the decades that followed. As discussed above, Paul Whitehead, from the University of Western Ontario, and his colleague Patricia Sealy argued that deinstitutionalization was not implemented consistently across geographic areas, with different provinces showing variation in their timing and approaches (as cited by Davies et al., 2016). In the years following the accidental discovery of the antipsychotic drugs, there was rapid closure of beds in psychiatric hospitals across Canada. However, there was a concomitant increase in beds in general hospitals for use by psychiatric patients. As well, because psychiatric in-patients were discharged into the community at a time when growth in community mental health services was slow across Canada, the unintended effect of releasing people incapable of caring for themselves without support, in many cases, resulted in homelessness (see photo).

TABLE 16.2

Commonly Prescribed Psychotropic Drugs
Source: Reprinted with permission of John Wiley & Sons, Inc., from Kowalski, R., & Westen, D. (2011). Psychology (6th ed.). Hoboken, NJ: Wiley, p. 598

Symptom	Type of Medication	Examples
Psychosis	Antipsychotics	chlorpromazine (Thorazine) clozapine (Clozaril)
Depression	Tricyclic antidepressants MAO inhibitors	trazodone (Desyrel) amitriptyline (Elavil) desipramine (Norpramin) phenelzine (Nardil)
Mania	Mood stabilizers	lithium (Lithonate)
Anxiety	Anxiolitics Antidepressants	benzodiazepines (Valium, Xanax) fluoxetine (Prozac)

Skyak/Getty Images

Mental illness and homelessness **Individuals suffering from severe mental illness are disproportionally and more seriously affected by homelessness than those without mental illness.**

The classic antipsychotic drugs include chlorpromazine (trade name: Thorazine), thioridazine (Mellaril), and haloperidol (Haldol). These drugs help patients experiencing positive symptoms such as hallucinations and paranoia. However, patients experiencing negative symptoms often get little relief from the classic antipsychotic drugs. New generation drugs, the atypical antipsychotics, such as clozapine (Clozaril), resperidone (Risperdal), and olanzapine (Zyprexa), help patients who do not respond to the typical antipsychotics, as well as some with negative symptoms such as apathy, diminished affect, and poverty of speech (Marder, 2014). These drugs have also proven to be particularly effective for schizophrenics who have persistent suicidal thoughts or who engage in self-injurious behaviours (Pompili et al., 2016). Studies indicate that antipsychotic drugs reduce psychotic symptoms within one and eight weeks, to lesser or greater degrees from one individual to another, about 70 percent of the time (Zhang, 2016).

It is thought that antipsychotic drugs work by blocking dopamine receptors, thereby blocking dopamine activity at the receptor sites (Ogino et al., 2014), although the exact nature of the relationship between the neurochemical effect and clinical outcomes is as yet unclear (Weinstein et al., 2017; Winton-Brown, Fusar-Poli, Ungless, & Howes, 2014). It is important to note, however, that the dopamine hypothesis does not necessarily argue for more dopamine, but rather for more activity at the receptor sites. Moreover, atypical antipsychotics affect both dopamine and serotonin activity (Meltzer, 2013), and more recent research has identified decreased glutamate activity as playing an important role (Laruelle, 2014). Therefore, a number of neurotransmitter systems have been implicated. A number of researchers have argued that the drug companies have pushed the dopamine hypothesis because they have made billions of dollars on the drugs they sell; these authors contend that this has prevented other, perhaps more productive, solutions from being pursued (Mosher, Gosden, & Beder, 2013).

Atypical antipsychotics tend to be the front-line treatment for schizophrenia (Meltzer, 2013; Miyake, Miyamoto, & Jarskog, 2012). There is controversy about whether the second-generation drugs are superior to the classic antipsychotic drugs, with some researchers suggesting the atypical antipsychotics are superior to the classic antipsychotic drugs, and other researchers suggesting no difference in effectiveness between the classic and second-generation drugs (Julien et al., 2013; Meltzer, 2013). This debate aside, determining a single course of treatment for a given patient is very difficult. Given the multiple and complex symptoms associated with schizophrenia, the wide individual variation in the response to drugs (in terms of both efficacy and side effects), as well as the diversity of treatment options, this disorder is very difficult to treat (Yin et al., 2017; Massey, Li, & Meltzer, 2014). Long-term outcome is highly correlated with early diagnosis, and treating negative symptoms continues to be an obstacle (Gaebel et al., 2014) as does conceptualizing and understanding treatment-resistant schizophrenia (Gillespie et al., 2017).

Antipsychotic drugs may also cause serious side effects (Flanagan & Ronaldson, 2016). The classic antipsychotic drugs can produce severe movement abnormalities, including severe shaking, contractions of the face and body, and extreme restlessness (Geddes, Stroup, & Lieberman, 2011); can cause Parkinson-like symptoms such as tremors, posture imbalance, and muscle rigidity (recall that Parkinson's is caused by too little dopamine); and in serious cases can cause a disorder called tardive dyskinesia. *Tardive dyskinesia* is a neurological disorder marked by involuntary repetitive tic-like symptoms affecting the tongue, lips, and face, as well as the trunk and extremities. Symptoms often persist well after the medication that caused the disorder has been terminated (Chandra, Seth, Mehta, & Dave, 2017). The atypical antipsychotics do not inevitably come with the risk of movement abnormalities, although they can also have unwanted movement side effects (Chandra et al., 2017), as well as other side effects. For example, in a small percentage of cases—about 1 percent—clozapine lowers the white count in the blood cells to dangerously low numbers and the patient becomes highly susceptible to infection. As a result, those who take the drug have to take regular blood tests to monitor for this toxic reaction (Girardin et al., 2014). As well, the atypical antipsychotics in general are associated with obesity and diabetes (Wei Xin Chong et al., 2016). Side effects have serious consequences; due to the unpleasant side effects associated with these drugs, many patients discontinue their medications and relapse within a year (Kishimoto, 2013).

Antidepressants

Americans are among the biggest consumers of antidepressants in the world (used by 11 percent of the population) with Canadians not far behind (9 percent of the population) (Kantor et al., 2015; OECD, 2013). Antidepressants are primarily used for treating mood disorders, particularly depression, but some antidepressants (SSRIs, as explained below) are also useful for treating anxiety, particularly generalized anxiety disorder, OCD, and panic disorder (Gordon, Brandish, & Baldwin, 2016). Antidepressants primarily target the serotonin and norepinephrine pathways (Fakhoury, 2016). Those with more severe depression tend to respond best to antidepressants, whereas those with mild to moderate depression receive little to some benefit (Cameron, Reid, & MacGillivray, 2014).

Marco Rosario Venturini Autieri/Getty Images

Antidepressant drugs **The antidepressant fluoxetine (Prozac) works by blocking the reabsorption of the neurotransmitter serotonin from the synapse. By keeping serotonin in the synapse longer, the serotonin has a stronger effect.**

Prior to 1987, two classes of antidepressants were commonly prescribed: tricyclics (Elavil) and MAO inhibitors (Nardil). Tricyclics work by blocking the reuptake of serotonin and norepinephrine. The result is elevation of synaptic concentrations of these neurotransmitters in the synapse and increasing activity at both receptor sites (Nelson, 2013). Monoamine oxidase inhibitors (MAOIs) prevent the monoamine oxidase enzymes from breaking down norepinephrine, serotonin, and dopamine, thereby increasing their availability (Wimbiscus et al., 2010). Traditionally, MAOs were a last line of defence because of dietary restrictions associated with their use to prevent the spiking of blood pressure. There is now some question of whether this restriction is as necessary as once believed (Grady & Stahl, 2012).

Fluoxetine (Prozac), sertraline (Zoloft), and paroxetine (Paxil) work by blocking the reabsorption of serotonin from the synapse (see photo). For this reason, this group of drugs is called selective serotonin reuptake inhibitors (SSRIs). These drugs exert their effect by keeping serotonin in the synapse for longer, enabling it to exert a stronger effect (see Your Brain and Behaviour 16.1). SSRIs are relatively fast acting, with approximately 60 percent of patients noting improvement after two weeks (Duman et al., 2016; Wilson, Chen, & Darji, 2016).

SNRIs or serotonin reuptake inhibitors, including drugs such as venlafaxine (Effexor) and duloxetine (Celexa), act by blocking the reabsorption of serotonin and norepinephrine from the synapse. There is some evidence that this class of drugs is somewhat more effective at treating symptoms of depression than the SSRIs (Blier, 2016). However, SNRIs have more side effects than the SSRIs, including increased risk for diabetes and cardiovascular problems (Bezchlibnyk-Butler, Jeffries, Procyshyn, & Virani, 2013).

Research shows that SSRIs are equally as effective as tricyclics, but without the side effects, and their use is associated with better rates of compliance (Von Wolff et al., 2013). Since the side effects of tricyclics can include erectile dysfunction, reduced sex drive, heart arrhythmias, tremors, and confusion, SSRIs are highly desirable as a first line of treatment. In fact, the Canadian Network for Mood and Anxiety Treatments (CANMAT) partnered with

the Canadian Psychiatric Association in 2001 to produce clinical guidelines for the treatment of depression. This body has approved the use of second-generation antidepressants (SSRIs and SNRIs) over first-generation antidepressants (tricyclics and MAOIs) as a first-line approach (Lam et al., 2016).

Ketamine, a nonbarbituate drug previously used as an anesthetic for humans or for veterinary use, and with a history of abuse as a club drug, is being touted by some as the drug of choice for high-risk patients suffering from treatment-resistant mood disorders such as bipolar or major depressive disorder. At low doses, ketamine exerts an antidepressant effect that takes effect in minutes to hours (rather than weeks to months) and therefore some researchers argue that ketamine (brand name Ketalar) is a rapid, potent, effective drug option for one-time use in these patients as well as for suicidal patients (Tuck & Ghazali, 2017; Abdallah, Sanacora, Duman, & Krystal, 2015). However, this claim is controversial because other researchers (Tracy, Caddy, & Shergill, 2016) argue that the drug is classified in Canada by the Controlled Drug and Substances Act as a Schedule 1 narcotic. (Schedule I drugs are substances that must be prescribed following a diagnosis and must be used in a controlled or regulated setting.) Tracy et al. argue that ketamine has recognized dangerous side effects associated with neurotoxicity and abuse/addiction and has limited data on ongoing usage in humans. Others feel that the drug has potential in long-term depression treatment as a bridging drug and can be used until longer-acting SSRIs or SNRIs take effect (Wilson, Rosenberg, & Ning, 2016).

Also of concern in the last 10 years or so has been the finding that antidepressants, particularly SSRIs, increase the risk for suicide especially among children, adolescents, and emerging adults (Hetrick et al., 2017). More recent evidence suggests that this risk is heightened within the first month or two of the patient beginning the course of treatment (Gibbons et al., 2015). Other studies have failed to replicate this claim for increased risk and instead argue that, after controlling for severity of depression, the risk for suicide actually goes down (Garland, Kutcher, Virani, & Elbe, 2016; Leon et al., 2011). Nevertheless, patients with serious depression need to be closely monitored when they begin treatment (Gibbons et al., 2015). Regulatory warnings from the U.S. Food and Drug Administration, as well as from Health Canada, have resulted in a black box warning for all antidepressant use in those under 18 years of age. Blackbox warnings are the strictest labeling requirment used by the FDA to highlight serious or life-threatening side effects from drugs. Many are questioning the wisdom of this caution, arguing that there is no evidence for increased risk in this age group, and that untreated individuals are at greater risk than those being treated with antidepressants (Dubicka Cole-King, Reynolds, & Ramchandani, 2016; Sparks & Duncan, 2013).

Mood Stabilizers

Mood stabilizers are used to treat intense shifts in mood from one extreme state to another, preventing both depression and mania in those with bipolar disorder. Lithium, a salt, is the most commonly prescribed drug used to maintain a stable mood and to prevent future relapse or reoccurrence of depression or mania (Bauer & Gitlin, 2016; Chengappa & Gershon, 2013). Although lithium can be used to treat acute manic or depressive symptoms, antidepressants and antipsychotics are more commonly used (Schuepbach, 2015). Lithium has a number of serious side effects, including thyroid and kidney disease,

renal failure, loss of memory, cardiac arrhythmia, loss of bladder and bowel control, and more (Gitlin, 2016). As a consequence, alternatives to lithium have been identified. The most common alternative to lithium is valproate, an anticonvulsant agent. The direct mechanisms by which valproate stabilizes mood is unknown but probably involve a class of enzymes known as histone deacetylases (Chiu, Wang, Hunsberger, & Chuang, 2013; Schloesser, Martinowich, & Manji, 2012). Patients taking valproate are more likely to continue taking their medications than those taking lithium (Cipriani et al., 2013). Some patients are treated with a combination of lithium and valproate, or lithium in combination with other drugs (Chiu et al., 2013; Post et al., 2010). In addition to other concerns, but also because of the number of unpleasant side effects associated with these drugs, patients are frequently unwilling to adhere to their medical protocols; men are more likely than women to be non-compliant (Murru et al., 2011).

Antianxiety Drugs

The most popular antianxiety drugs are in the benzodiazepine family. Common drugs are diazepam (Valium), alprazolam (Xanax), and lorazepam (Ativan) (see photo). These drugs are often referred to collectively as tranquilizers. Unlike the drugs already discussed, which can take weeks to exert a full effect, antianxiety drugs immediately relieve the symptoms of anxiety (Bandelow et al., 2015). However, they are also fast-acting, and so their effects wear off within hours.

Tommaso Altamura/123 RF

Antianxiety drugs **Antianxiety drugs, such as diazepam (Valium), provide immediate relief of anxiety symptoms; however, their effects wear off quickly, often within hours.**

One problem with the benzodiazepine family of drugs is that they can be abused. When a patient takes an antianxiety drug, there is an almost immediate alleviation of anxiety; patients may therefore find themselves reaching for the medication with greater and greater frequency in an effort to seek immediate relief from their unpleasant symptoms, creating psychological dependence (Starcevic, 2014). As well, because the medication only alleviates the symptoms, the underlying causes for the anxiety are never addressed. These drugs also cause physiological dependence, and sudden cessation following heavy use is associated with withdrawal symptoms, including insomnia and increased anxiety (Lader &

Kyriacou, 2016).

Drug Therapy Summary

Many of the medications we have discussed have radically changed the lives of many people with psychological disorders. Drugs are increasingly being prescribed for every type of mental illness. Studies have indicated that psychiatrists prescribe on average two to three prescriptions per patient (Mojtabai & Olfson, 2010). One Canadian study showed that general practitioners in Quebec provided drug therapy to the majority of patients suffering from symptoms of depression and also prescribed antidepressants to treat unrelated symptoms such as insomnia and pain (Wong et al., 2016). However, it is important to note that these drugs do not work for everyone and often come with potential side effects that range from annoying to life threatening. It is therefore important to assess whether a particular drug is effective.

In order to assess the efficacy of a particular drug, researchers must take into account how many people who are untreated get better. That is, if we do nothing, how many people will spontaneously recover? It is also important to assess whether patients are responding to a particular drug or to the *idea* of the drug. That is, it is important to assess whether patients get better because they *expect* to get better, or they get better because the medication exerts an effect. For this reason, psychologists and physicians use the technique of the *double-blind procedure* (see **Figure 16.1**). In this method, some of the participants take the drug being tested and some take a placebo. (A **placebo** is an inactive substance that exerts no pharmacological effect.) Neither the patient nor the physician (or others dealing directly with the patient) know which drug the patient is taking.

> **placebo** an inactive substance, such as a sugar pill or distilled water, that mimics a drug but has no active ingredients.

Regardless of how effective a drug is, research shows that in most instances a combination of psychotherapy and drugs has a stronger effect than drugs alone (Oestergaard & Møldrup, 2011). And, as discussed throughout this book, it is also important to recall that many psychological disorders arise from the social conditions under which people live. It is therefore important that as a society we seek to redress the inequities and discrimination that underlie many of the mental illnesses people experience (Nazroo, Bhui, & Rhodes, 2020; Shim, Kho, & Murray-García, 2018).

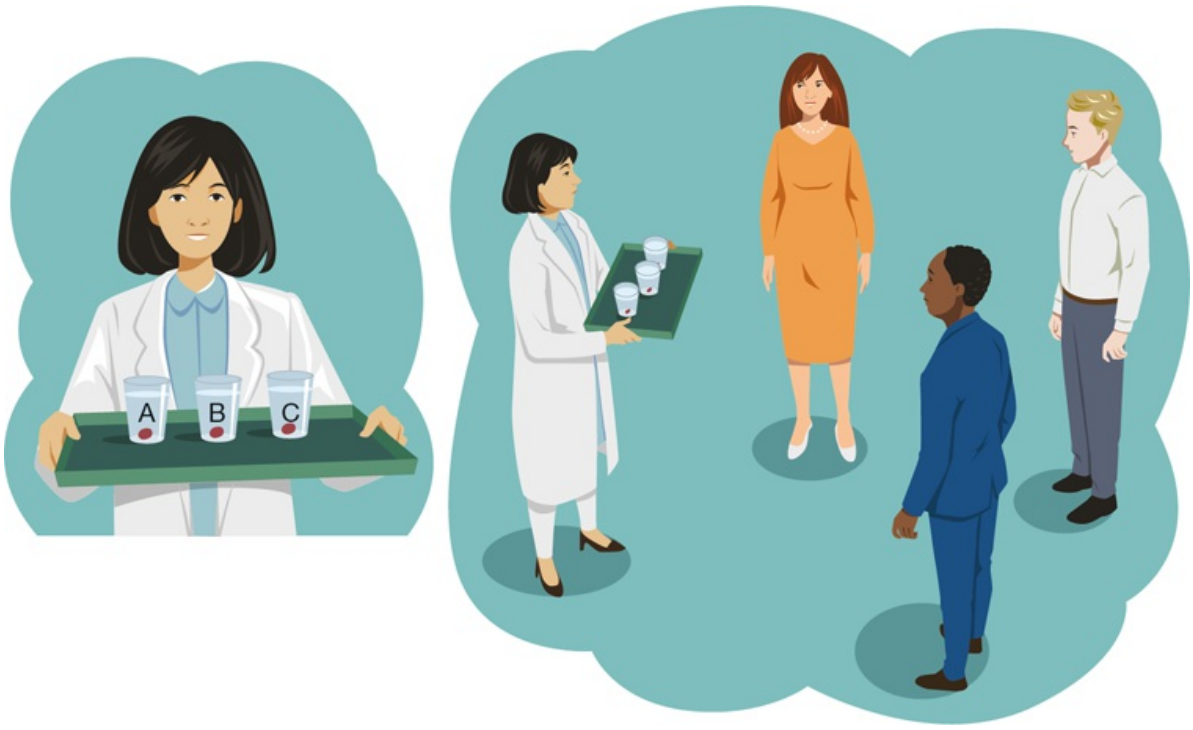

FIGURE 16.1 A double-blind study In order to reduce bias, in a double-blind study neither the patient nor the experimenter know which drug a patient is taking.

16.1 Your Brain and Behaviour

Taking an Antidepressant

When people have symptoms of depression so severe that they interfere with normal functioning, physicians will sometimes prescribe the use of antidepressant medication. Some of the most commonly prescribed antidepressants are selective serotonin reuptake inhibitors (SSRIs); these drugs are known by trade names such as Celexa, Paxil, Prozac, and Zoloft. The primary action of these drugs is to increase the availability of the neurotransmitter serotonin in the brain. Neurons that make serotonin are present in the brainstem raphe nuclei. These neurons send axon projections to the cortex, hippocampus, and amygdala, among other regions. SSRIs have a multitude of effects on these brain regions, although the precise mechanisms by which the drugs alleviate symptoms of depression are not known. How might antidepressant drugs work?

Questions

Which area of the cerebral cortex often shows reduced activity in people who are depressed?

What does it mean to say that a particular drug is a "serotonin reuptake inhibitor"?

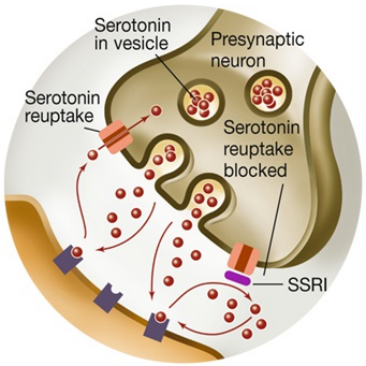
What is the role of the hippocampus in the recovery of someone taking

antidepressent medication to relieve depression?

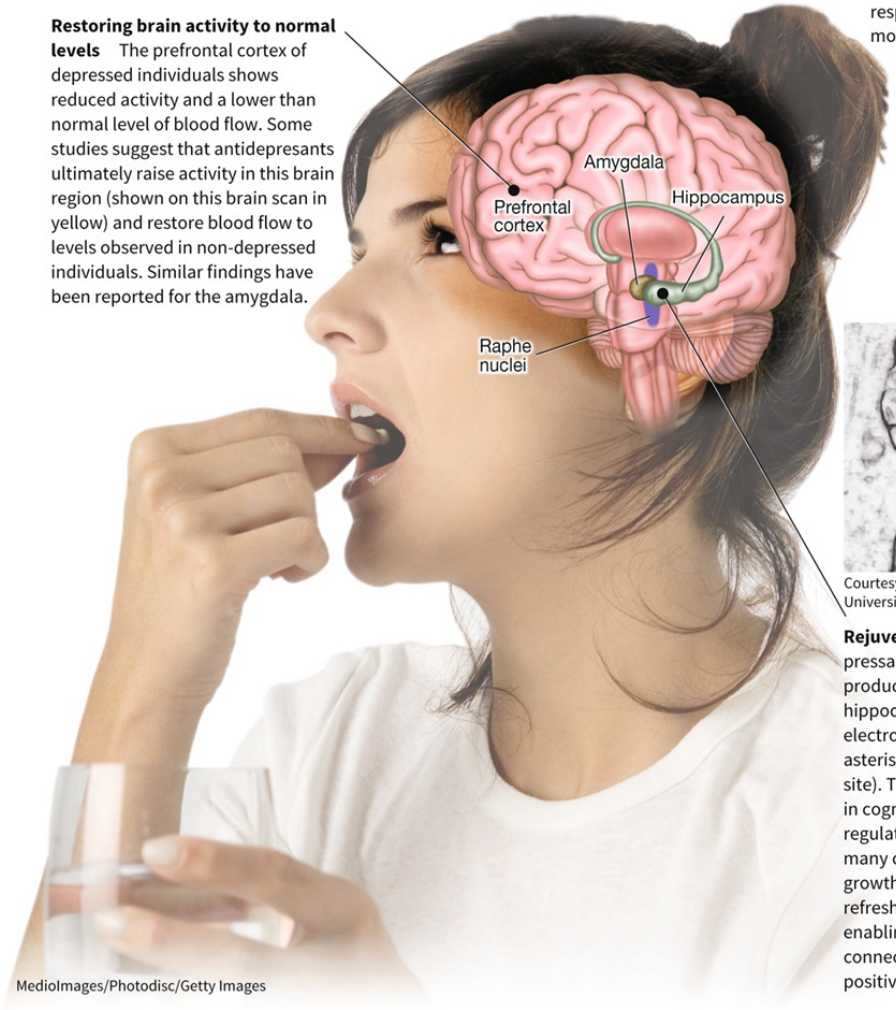
Newscom

From Paul Keedwell, Journal of Psychopharmacology 23(7):775-88, Figure 3, 2009, Sage Publications. ©2009 British Association for Psychopharmacology.

Restoring brain activity to normal levels The prefrontal cortex of depressed individuals shows reduced activity and a lower than normal level of blood flow. Some studies suggest that antidepresants ultimately raise activity in this brain region (shown on this brain scan in yellow) and restore blood flow to levels observed in non-depressed individuals. Similar findings have been reported for the amygdala.



Blocking serotonin reuptake By blocking key receptors, SSRIs prevent the reuptake, or retention, of serotonin by presynaptic neurons (shown in this illustration), thus freeing the neurotransmitter to better activate brain regions that are targets of serotonin axons, including the hippocampus and cerebral cortex. Depression relief, however, usually does not occur until someone has taken the drug for a few weeks, suggesting that some other mechanism may also be responsible for improving mood.



MedioImages/Photodisc/Getty Images

Rejuvenating the mind Antidepressant use stimulates the production of synapses in the hippocampus (shown here in this electron micrograph, with the asterisk indicating a postsynaptic site). The hippocampus plays a role in cognitive function and in regulating anxiety (a feature in many cases of depression). The growth of new synapses may refresh this important brain region, enabling the formation of new connections to support a more positive outlook.

Electroconvulsive Therapy

Another form of biological treatment is **electroconvulsive therapy (ECT)**, a technique first developed in the 1930s. ECT is used primarily for people who have severe depression. ECT is administered in the following manner. First, a strong muscle relaxant and usually a short-acting anesthetic are administered. Next, two electrodes are attached to the patient's forehead, and 65 to 140 volts of electricity are briefly passed through the brain (Pinna et

al., 2018). The procedure produces a brain seizure that lasts up to a few minutes. After an average of seven to nine ECT sessions, spaced two or three days apart, many patients feel considerably less depressed (see photo). ECT helps approximately 70 percent of depressed patients to improve (Perugi et al., 2012).

electroconvulsive therapy (ECT) use of electric shock to trigger a brain seizure in hopes of relieving abnormal functioning.

Will & Deni McIntyre/Science Source

ECT today As we can see with this patient, today's ECT treatments are conducted with considerable medical care and many safety precautions, and include procedures that help patients sleep throughout the procedure.

ECT is administered less often today than it was in the past, and is typically only used in treating severe depression that has not responded to other treatments. The procedure can negatively affect short-term memory (Merkl et al., 2011). Most such memories return, but some people who have gone through ECT report ongoing memory difficulties (Kroes et al., 2014; Freeman, Waite, & Easton, 2013). With the growing success of antidepressant medications and other forms of psychotherapy, fewer depressed patients now need this form of treatment. Nevertheless, ECT continues to be a viable treatment option when people have a severe depressive episode that does not respond to other forms of treatment or when they are suicidal. ECT is particularly effective in acute cases because it exerts a much more immediate effect than antidepressant drugs (McLoughlin, Kolshus, & Jelovac, 2017; Kellner et al., 2016).

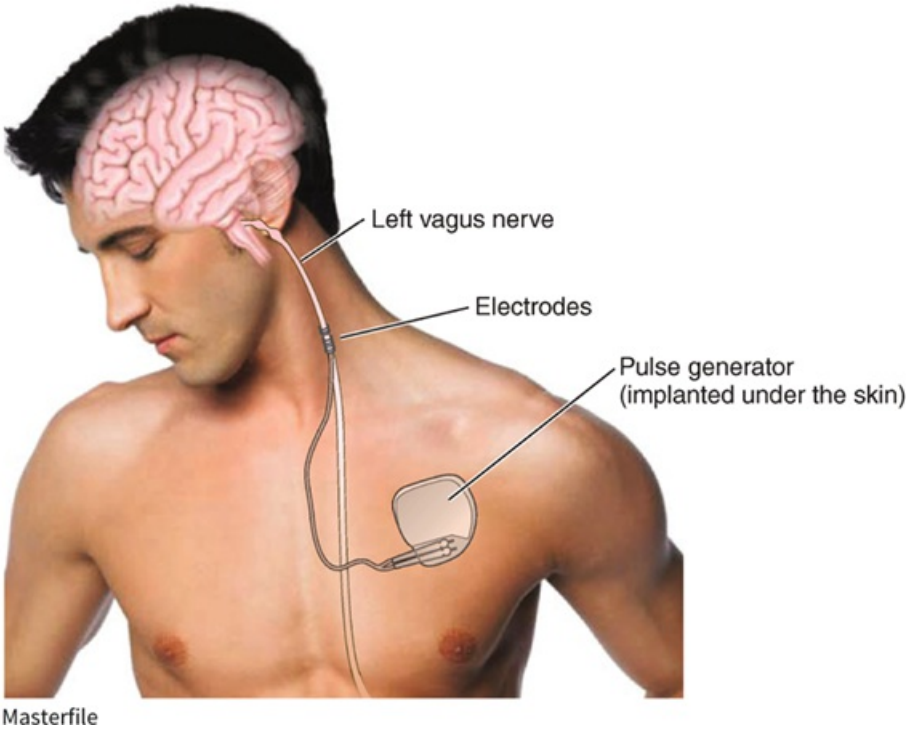
Although there is evidence to indicate that ECT is an effective treatment option in some cases of severe depression, for some the use of this treatment is contentious because the mechanism by which it alters mood is not well understood. Proponents argue that the seizure reestablishes biochemical and hormonal homeostasis in the brain in systems that control mood (Krishnan, 2016; McCall, Andrade, & Sienaert, 2014).

In recent years, two other biological approaches have been developed that also directly stimulate the brain. These approaches are *vagus nerve stimulation* and *transcranial magnetic stimulation*. These approaches appeal to many patients and clinicians because they are applied without the unpleasant side effects commonly associated with ECT.

Vagus Nerve Stimulation

The vagus nerve, the longest nerve in the human body, runs from the brain stem through the neck, down the chest, and on to the abdomen. In the **vagus nerve stimulation** procedure, a surgeon implants a small pacemaker-like device called a *pulse generator* under the skin of the chest. The surgeon then guides a wire, which extends from the pulse generator, up to the neck and attaches it to the left vagus nerve (see **Figure 16.2**). Electrical signals travel periodically from the pulse generator through the wire to the vagus nerve. In turn, the stimulated vagus nerve delivers electrical signals to the brain. These signals affect the mood centres of the brain.

vagus nerve stimulation a procedure in which an implanted device sends electrical signals to the brain through the vagus nerve; used to treat severe depression.



Masterfile

FIGURE 16.2 Vagus nerve stimulation In this procedure, an implanted pulse generator sends electrical signals to the left vagus nerve. That nerve then delivers

electrical signals to the brain, helping to reduce depression in many people.

In 1997, Health Canada approved the vagus nerve stimulation procedure for treating cases of otherwise intractable epilepsy. In 2001, after noting significant increases in positive mood in epileptics receiving the treatment, it was approved as a long-term treatment for severe treatment-resistant depression (Pisapia & Baltuch, 2015). Since this time, some research has found that the vagus nerve stimulation procedure provides significant symptomatic relief in as many as 65 percent of treatment-resistant depression cases (Howland et al., 2011).

Transcranial Magnetic Stimulation

In the **transcranial magnetic stimulation (TMS)** procedure, first developed in 1985, the clinician places an electromagnetic coil on or above the patient's head. The coil sends a current into the prefrontal cortex (Rotenberg, Horvath, & Pascual-Leone, 2014) (see photo). At least some parts of the prefrontal cortex of depressed people are underactive. TMS appears to increase neuron activity in those regions, thus helping to alleviate severe depression in about 65 percent of patients after it has been administered daily for two to four weeks (Perera et al., 2016). TMS was approved as a treatment option for major depressive disorder by Health Canada in 2002 (Blumberger & Daskalakis, 2016).

Early roots of psychosurgery? The hole in this 5100-year-old skull indicates that the individual underwent trephining, cutting away a circular section of the skull. Some historians believe that trephination was done to release the evil spirits that were thought to be responsible for mental dysfunction.

Psychosurgery

From time to time throughout the book, we have mentioned **psychosurgery**—brain-surgery procedures that can help some people with psychological disorders. Actually, the first use of brain surgery as a treatment for mental disorders was **trephining**, the prehistoric practice of chipping a hole in the skull to treat an injury or other disorder. Evidence indicates that trephining was used from prehistoric to medieval times (see photo).

psychosurgery brain surgery often used in hopes of relieving abnormal functioning.

trephining prehistoric practice of chipping a hole in the skull as a treatment for various brain conditions.

Many modern forms of psychosurgery are derived from a historic technique known as a **lobotomy**. In this procedure, the surgeon cuts the connections between the brain's frontal lobes and the lower centres of the brain. Lobotomies were widely used for a few decades after the procedure was developed in the 1930s, particularly in cases of schizophrenia. By the late 1950s, however, it had become clear that lobotomies were not as effective as many psychosurgeons had been claiming. Moreover, many patients who had undergone the surgery later suffered serious, irreversible effects to their intellect and personalities, including seizures, extreme listlessness, stupor, and in some cases, surgery resulted in death (Terrier, Lévêque, & Amelot, 2019; Barahal, 1958). Thus, use of this procedure declined during the mid- to late-1950s and 1960s as antipsychotic medications became more widely accepted and utilized (Schulkin, 2015).

lobotomy surgical practice of cutting the connections between the frontal lobe and the

lower centres of the brain.

Psychosurgery today is much more precise than the lobotomies of the past. It has fewer negative effects, and it is beneficial for some psychological and neurological disorders. One form of psychosurgery that is currently receiving considerable attention is **deep brain stimulation**—a procedure applied in cases of severe depression, Parkinson's disease, and brain seizure disorder (epilepsy). In deep brain stimulation, a surgeon drills two tiny holes into the patient's skull and implants electrodes in areas of the brain that have been implicated in the disorder. The electrodes are connected to a battery, or "pacemaker," that is implanted in the patient's chest (for men) or stomach (for women). The pacemaker powers the electrodes, sending a steady stream of low-voltage electricity to the problematic brain areas (Miocinovic, Somayajula, Chitnis, & Vitek, 2013; see images). In many cases, this repeated stimulation readjusts the person's brain activity and, over time, brings significant improvement (Chen et al., 2013; Blomstedt et al., 2011; Hamani et al., 2011). Although such implants have offered promising results, at present they are still considered experimental. Thus, this approach is used infrequently, particularly in cases of depression, and usually only after the severe disorder has continued for years without responding to other forms of treatment.

Biological Treatments in Perspective

Biological treatments for psychological disorders, particularly drug treatments, are very

popular. They often bring great relief when other approaches have failed. However, the treatments have key limitations. As you have read, they can produce significant side effects. Moreover, more often than not, biological interventions alone are not a sufficient treatment for psychological disorders (Emmelkamp et al., 2014; Rosenberg & Kosslyn, 2014). Indeed, as we have seen throughout the textbook, the connections in our brains unfold partly in response to the environmental experiences that we have all through our lives, beginning in utero (Sale, Berardi, & Maffei, 2014).

Evidence is mounting, in fact, that just as behaviour can respond to changes in our brain chemistry, so too does our brain chemistry respond to changes in behaviour. One study, for example, found that people with depression who responded to psychotherapy came to show brain responses similar to those of healthy, non-depressed individuals. In contrast, depressed individuals who did not respond to psychotherapy continued to show the abnormal brain patterns that typically accompany depression (Yoshimura et al., 2014). In short, just as negative experiences can interact with brain activity to produce abnormal functioning, positive experiences can interact with the brain to make our functioning more normal (Lopizzo et al., 2015).

What Do You Think? • Are today's clinicians and their clients too reliant on drugs as a treatment? Why or why not?

Psychodynamic Therapies

LEARNING OBJECTIVE 3

Describe the psychodynamic treatments for psychological disorders.

Following the principles of the psychodynamic model, psychodynamic therapists contend that today's emotional disorder is the result of yesterday's emotional trauma. A variety of psychodynamic therapies are now being practised, ranging from classical *Freudian psychoanalysis* to modern therapies such as *short-term psychodynamic therapy* and *relational psychoanalytic therapy*. All share the goals of helping clients to uncover past traumatic events and the inner conflicts that have resulted from them; to resolve, or settle, those conflicts; and to resume interrupted personal development. Psychodynamic therapists of different theoretical persuasions might focus on different conflicts, but they tend to use similar techniques.

Techniques of Psychodynamic Therapies

Psychodynamic therapists try to subtly guide their discussions with clients so that the clients discover their underlying problems for themselves (see photo). How do they do this? In part, they rely on such techniques as *free association*, *therapist interpretation*, *catharsis*, and *working through* (Gabbard, 2017; Summers & Barber, 2013).

Wavebreak Media ltd / Alamy Stock Photo

Psychodynamic techniques In order to help clients come to an appropriate understanding of their underlying problems, psychodynamic therapists interpret what the clients tell them.

Free Association

In psychodynamic therapies, the client is responsible for starting and leading each discussion. The therapist tells the individual to describe any thoughts or feelings that come to mind, even if they seem unimportant. This is the process known as **free association**. The therapist then probes the client's associations in the hope that they will eventually reveal the unconscious events that underlie the individual's problem.

free association psychodynamic therapy technique of allowing clients to freely talk about whatever they want.

Therapist Interpretation

Psychodynamic therapists share their interpretations of a client's associations with the client only when they think the individual is ready to hear them. The interpretations of three phenomena—*resistance*, *transference*, and *dreams*—are thought to be of special value.

Resistance Individuals demonstrate **resistance** when they encounter a block in their free associations or change the subject to avoid a potentially painful discussion. The

therapist remains on the lookout for resistance, which is usually unconscious, and may point it out to the client and interpret it.

Transference Psychodynamic therapists also believe that clients act and feel toward the therapist as they do toward important figures in their lives, past and present. This displacement of feelings is called **transference**. By interpreting transference behaviour, therapists may help individuals better understand how they unconsciously feel toward a parent or some other key person.

Dream interpretation Freud (1924) called dreams the "royal road to the unconscious." He believed that repression and other defence mechanisms operate ineffectively during sleep. Thus, a client's dreams can help reveal the person's unconscious instincts, needs, and wishes. Of course the dreams must be correctly interpreted. Freud distinguished a dream's *manifest content* (the consciously remembered dream) from its *latent content* (the symbolic meaning).

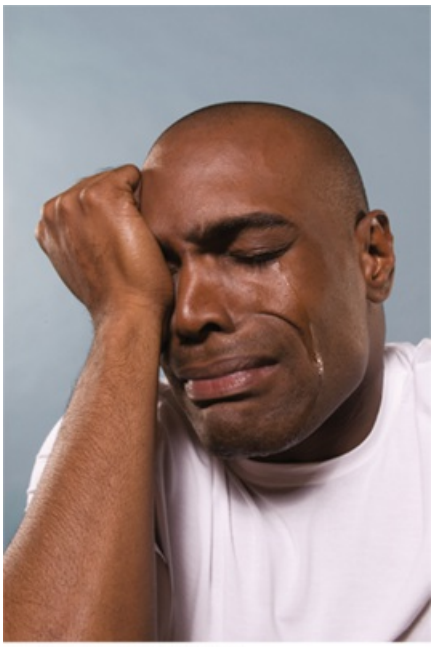
resistance practice in which clients encounter a block in their free associations or change the subject to avoid a potentially painful discussion.

transference process through which clients come to act and feel toward the therapist as they did toward important figures in their childhood.

Catharsis

Psychodynamic therapists believe that individuals must experience **catharsis** if they are to resolve internal conflicts and overcome their problems. That is, they must re-experience their past repressed feelings. Emotional catharsis must accompany intellectual insight for genuine progress to be achieved.

catharsis reliving of past repressed feelings as a means of settling internal conflicts and overcoming problems.



PM Images/Getty Images

Catharsis **Patients must re-experience past feelings in order to resolve internal conflicts and overcome their problems. Catharsis must be accompanied by intellectual insight.**

Working Through

A single session of interpretation and catharsis will not change a person. For deep and lasting insight to be gained, the client and therapist must *work through*, or examine, the same issues over and over, across many sessions, trying on the insights offered through therapy, each time with new and sharper clarity (Gabbard, 2017; Summers & Barber, 2013).

Short-Term Psychodynamic Therapies

It should be clear by now that Freud's psychoanalytic therapy takes time. However, over the years the public and health care providers increased their demand for more efficient, time-limited psychotherapies. The pressure for briefer therapy is also present in Canada, though driven more by limits of coverage for therapy either through employee assistance programs or health care insurance providers. As a result, several efforts emerged to make psychodynamic therapy shorter, more efficient, and more cost-effective. In brief versions of psychodynamic therapy, called *short-term psychodynamic therapy*, clients focus on a single problem—a *dynamic focus*—such as excessive dependence on other people (Wolitzky, 2011). The therapist and client centre their discussions on this problem and work only on issues that relate to it. A relatively small number of studies have tested the effectiveness of these short-term psychodynamic therapies. Their findings, however, suggest that the approaches are sometimes quite helpful (Fjeldstad, Høglend, & Lorentzen, 2015; Wolitzky, 2011).

Relational Psychoanalytic Therapy

Whereas Freud believed that psychodynamic therapists should take on the role of a neutral, distant expert during a treatment session, a current school of psychodynamic therapy called **relational psychoanalytic therapy** argues that therapists are key figures in the lives of clients—figures whose reactions and beliefs should be directly included in the therapy process (Luborsky, O'Reilly-Landry, & Arlow, 2011). Thus, a key principle of relational psychoanalytic therapy is that therapists should also disclose things about themselves, particularly their own reactions to patients, and try to establish more equal relationships with clients as opposed to the distant analytic relationships typical of standard psychoanalysis (Curtis & Hirsch, 2011).

relational psychoanalytic therapy a school of psychodynamic therapy holding that therapists should work to form more equal relationships with clients.

Psychodynamic Therapies in Perspective

Freud and his followers have had a major impact on treatment. They were the first practitioners to demonstrate the value of systematically applying both theory and techniques to treatment. Moreover, their approaches were the first to clarify the potential of psychological, as opposed to biological, treatment. In fact their ideas have served as a starting point for many other psychological treatments (Gabbard, 2017; Summers & Barber, 2013).

The efficacy of psychodynamic therapies has been debated, with some researchers reporting a lack of effectiveness (Wampold, Hollon, & Hill, 2011), while others report significant data indicating that psychodynamic psychotherapy is superior to, or at least as effective as, other therapeutic approaches (Steinert et al., 2017; Shedler, 2010), especially for short-term psychodynamic psychotherapy (Driessen et al., 2015) (see Psychology Around Us 16.1). For the first half of the twentieth century, the value of these approaches was supported mostly by the case studies of enthusiastic clinicians and by uncontrolled research studies. Controlled investigations have been conducted only since the 1950s, and, with the exception of short-term psychodynamic therapies, only a small number of such studies have found psychodynamic therapies to be more effective than no treatment or placebo treatments (Shedler, 2010), although other studies report that longer term psychodynamic therapies are more effective than short-term psychodynamic therapies (Huber et al., 2013). Currently, approximately, 15 percent of today's clinical psychologists identify themselves as psychodynamic therapists (Sharf, 2012; Prochaska & Norcross, 2010).

16.1 Psychology Around Us

Psychodynamic Treatments for Borderline Personality Disorder

Personality disorders have been historically very difficult to treat, except for third-wave cognitive behavioural therapeutic approaches such as dialectic behaviour therapy (see Positive Psychology 16.1), and they are often unresponsive to common mood and anxiety treatments (Keefe et al., 2018; McMain et al., 2012). Borderline personality disorder in particular is marked by ongoing volatility in mood, unstable

relationships, and impulsive behaviour. Among other symptoms, persons diagnosed with this disorder often experience feelings of emptiness, paranoid thoughts, and intense anger issues, making this disorder difficult to treat over the long term. Shelly McMain at the University of Toronto and colleagues from the United States, Germany, and Israel carried out a systematic meta-analysis evaluating the effectiveness of psychodynamic therapies as a way of treating personality disorders (Keefe et al., 2020). Although psychodynamic therapies have been claimed by therapists to facilitate or predict improvements in general functioning and to reduce undesirable symptoms in those diagnosed with borderline personality disorder (Høglend & Hagtvet, 2019), prior to this evaluation, no comprehensive meta-analysis had been undertaken of previous studies examining psychodynamic therapy used with clients comprising this population. In short, the study showed no significant advantage of psychodynamic approaches over other legitimate approaches during active therapy but did show more lasting effects at the post-treatment follow-up. The authors stated a need for additional studies with more rigorous control groups.

7. List and describe psychodynamic therapy techniques.

What Do You Think? • Remember Romy, in our chapter opener. In treating Romy's psychological distress, where might a Freudian psychoanalyst start? Would this analyst be likely to achieve the results described in the time frame identified? Why or why not?

Behavioural Therapies

LEARNING OBJECTIVE 4

Describe the behavioural treatments for psychological disorders.

Behavioural theories and treatments today are usually part of the *cognitive-behavioural model*—the perspective that combines behavioural and cognitive principles to explain and treat psychological disorders. For many years, however, behavioural treatments were applied on their own, and, even today, there are times when behavioural interventions alone are sufficient to treat certain problems. Thus, in this section we will look at behavioural therapies exclusively. We will then move on to cognitive-behavioural therapies in the next section.

As you may recall from Chapter 15, behaviourists contend that the symptoms of a psychological disorder are learned behaviours acquired through the same conditioning processes that produce normal behaviours (Staddon, 2014). The goal of behavioural therapy is to identify the client's specific problem-causing behaviours and to replace them with more adaptive behaviours. The therapist's attitude toward the client is that of a teacher, rather than a healer. Behavioural techniques fall into three categories: *classical conditioning*, *operant conditioning*, and *modelling*.

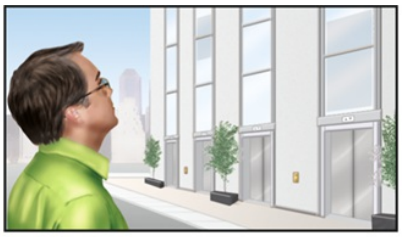
Classical Conditioning Techniques

Classical conditioning treatments are intended to change clients' dysfunctional reactions to stimuli. One treatment, described in Chapter 7, is *systematic desensitization*. This step-by-step process is aimed at teaching people with phobias to react with calm instead of fear to the objects or situations they dread (Fishman, Rego, & Muller, 2011; Wolpe, 1997a, 1997b, 1995, 1990). Clients first are trained in deep-muscle relaxation, through deep breathing, calming mental imagery, and systematic tensing and releasing of muscles. Next, they construct a *fear hierarchy* in which they list objects or situations associated with their phobia, starting with the least feared and ending with the most feared. For a client with a phobia of elevators, for example, looking at an elevator on the outside of a building a block away might be low on the fear hierarchy; watching the elevator doors close while inside the elevator might be near the top (see **Figure 16.3**). Finally, either in imagination or physically, clients confront each item on the hierarchy while they are in a state of deep relaxation, starting with the least fearful and then moving on up the list.

Least

Amount of anxiety

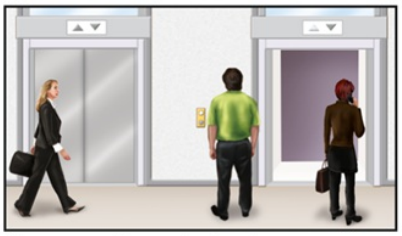
Most



Looking at a building with outside elevators

Approaching a bank of elevator doors

Pressing the elevator call button



Doors open to empty elevator

Stepping onto elevator with a few other people

In a crowded elevator as doors close

FIGURE 16.3 Fear hierarchy Systematic desensitization uses classical conditioning principles to reduce a person's fears. Starting with the least stressful situation on his fear hierarchy, a man with a fear of riding in an elevator is exposed to each item on the hierarchy while applying relaxation techniques.

Source: Table 17-2: Reprinted with permission of John Wiley & Sons, Inc., from Kowalski, R., & Westen, D. (2009). *Psychology* (5th ed.). Hoboken, NJ: Wiley, p. 574.

Research has repeatedly found that systematic desensitization and other classical conditioning techniques reduce phobic reactions more effectively than placebo treatments or no treatment at all (Olatunji et al., 2011; Kraft & Kraft, 2010). These techniques have also been helpful in treating several other kinds of problems, including sexual dysfunctions, posttraumatic stress disorder, agoraphobia, and asthma attacks (Foa & McLean, 2016). Because desensitization techniques expose individuals to the objects or situations they fear, and because this exposure seems so critical to implement, these and related approaches are often referred to as *exposure* treatments (Maren & Holmes, 2016; Abramowitz, 2013).

An opposite use of classical conditioning is known as **aversion therapy**. Here, clients *acquire* anxiety responses to stimuli that they have been finding too attractive. As shown in **Figure 16.4**, this approach has been used with people who want to stop excessive drinking, for example, (Brewer, Streel, & Skinner, 2017). In repeated sessions, the clients may be given an electric shock, a nausea-producing drug, or some other noxious stimulus whenever they reach for a drink. Aversion therapy has also been applied to help eliminate such undesirable behaviours as sexual paraphilias, smoking, and self-multilation behaviours in children diagnosed with autism (Minshawi et al, 2015; Fisher & Maggi, 2014; Carim-Todd, Mitchell, & Oken, 2013). However, the effects of this approach are typically short-lived, especially for those individuals who are aware that it is the drugs and not the alcohol, smoking, or other behaviour that is actually causing their nausea (Zindel & Kranzler, 2014).

aversion therapy therapy designed to help clients to acquire anxiety responses to stimuli that the clients have been finding too attractive.

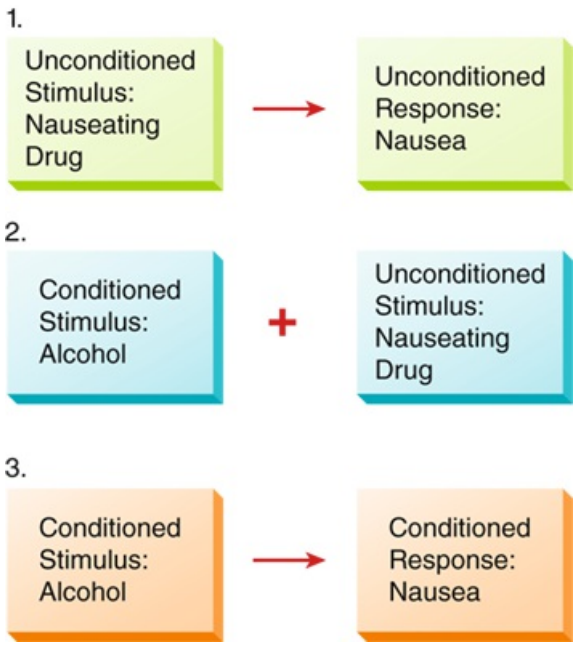


FIGURE 16.4 Aversion therapy **Aversion therapy uses classical conditioning principles to create a negative response to a stimulus a person would like to avoid, such as alcohol.**

Operant Conditioning Techniques

In operant conditioning treatments, therapists consistently provide rewards for appropriate behaviour and withhold rewards for inappropriate behaviour. This technique has been employed frequently, and often successfully, with hospitalized patients experiencing psychosis (Glynn, 2014). For example, when such patients speak coherently and behave normally, they are rewarded with food, privileges, attention, or something else they value. Conversely, patients receive no rewards when they speak bizarrely or display other psychotic behaviours.

Parents, teachers, and therapists have successfully used operant conditioning techniques to change problem behaviours in children (such as repeated tantrums) and to teach skills to individuals diagnosed with autism or intellectual disabilities (Hersen, Eisler, & Miller, 2016; Martin & Pear, 2016; Soorya, Carpenter, & Romanczyk, 2011). Rewards in such cases have included food, recreation time, social rewards, and television watching.

HD57life/Alamy Stock Photo

We're all familiar with token economies **The token economies applied in various mental health settings operate just like the star system that most of us were exposed to in elementary school. At school, however, good work was rewarded with stars instead of tokens, and numerous stars added up to a certificate instead of privileges, treats, or other rewards.**

Operant conditioning techniques typically work best in institutions or schools, where a person's behaviour can be reinforced systematically throughout the day. Often, an entire ward or classroom is converted into an operant conditioning arena. In many such programs, desirable behaviour is reinforced with tokens that can later be exchanged for food, privileges, or other rewards (Ayllon & Azrin, 1968). Programs of this sort are called **token economy** programs (Doll, McLaughlin, & Barretto, 2013) (see photo).

> **token economy** operant conditioning therapy program in which participants receive tokens (that can be traded for rewards) when they display desired behaviours.

Behavioural techniques based on operant conditioning have also been useful for treating depression (Lazzari, Egan, & Rees, 2011). Recall from Chapter 15 that depression is often associated with a decline in pleasant activities and withdrawal. To deal with these behaviours, therapists may work with depressed individuals to identify activities the clients enjoy and then guide the individuals in adding the activities back into their lives (Carvalho & Hopko, 2011).

Modelling Techniques

Modelling therapy was first developed by the pioneering Canadian-born social learning theorist Albert Bandura (1977, 1969). Here, therapists demonstrate appropriate behaviours for clients. Then the clients, through a process of imitation and rehearsal, acquire the ability to perform the behaviours in their own lives. This procedure has been used to treat phobias, for example. When therapists repeatedly display calm emotions

while confronting objects that are feared by phobic clients, many clients are able to overcome their phobias (Rosenthal & Bandura, 1978; Bandura, Adams, & Beyer, 1977).

Behavioural therapists have also used modelling to help people acquire or improve their social skills and assertiveness. In an approach called **social skills training**, for example, therapists point out the social deficits of clients and then role-play social situations with the clients, typically modelling more appropriate social behaviours for them. Ultimately, the clients practise the behaviours in real-life situations (Trower & Hollin, 2013). For example, the following dialogue demonstrates how a therapist might guide a client who is a male university student who has difficulty making dates with women:

Client: By the way, [Pause] I don't suppose you want to go out Saturday night?

Therapist: Up to actually asking for the date you were very good. However, if I were the girl, I think I might have been a bit offended when you said, "By the way." It's like you're asking her out is pretty casual. Also, the way you phrased the question, you were kind of suggesting to her that she doesn't want to go out with you. Pretend for the moment I'm you. Now, how does this sound: "There is a movie at the Varsity Theatre this Saturday that I want to see. If you don't have other plans, I'd very much like to take you."

Client: That sounded good. Like you were sure of yourself and liked the girl too.

Therapist: Why don't you try it.

Client: You know that movie at the Varsity? Well, I'd like to go, and I'd like to take you Saturday, if you don't have anything better to do.

Therapist: Well, that certainly was better. Your tone of voice was especially good. But the last line, "if you don't have anything better to do," sounds like you don't think you have too much to offer. Why not run through it one more time.

Client: I'd like to see the show at the Varsity, Saturday, and, if you haven't made other plans, I'd like to take you.

Therapist: Much better. Excellent, in fact. You were confident, forceful, and sincere.

Role-playing Asking someone on a date requires practice for some individuals.

Using a combined strategy of modelling, rehearsal, feedback, and practice, therapists have successfully taught social and assertion skills to shy, passive, or socially isolated people. These techniques can help people who have a pattern of violent outbursts after building up resentment (rather than asserting themselves) over perceived social slights (Lochman, Barry, Powerll, & Young, 2010). The approach has also been used to improve the social skills of children and adults who experience depression, anxiety, or other psychological problems (Ogden, 2011; Ishikawa et al., 2010).

Behavioural Therapies in Perspective

Behavioural interventions have been among the most widely researched treatment approaches in the clinical field (Wilson, 2011). Certainly, they lend themselves to research more than the psychodynamic approaches do. The removal of symptoms—the criterion of progress in behavioural therapy—is easier to observe and measure than the largely internalized criterion of conflict resolution—the psychodynamic criterion of improvement. Moreover, behavioural approaches have been demonstrated to be effective for numerous problems, including reducing or eliminating specific fears, minimizing social deficits, and addressing issues arising from intellectual disabilities (Nathan & Gorman, 2015; Wilson, 2011).

Cynthia Dopkin/Science Source

Behavioural interventions **Time out is a popular behavioural technique for disciplining young children and is largely effective due to its focus on a specific and current behaviour.**

At the same time, behavioural therapies have certain limitations. First, the improvements they bring about do not always maintain themselves without further interventions (see photo). Second, behavioural therapies, by themselves, do not appear to be particularly effective when psychological disorders are broad or vaguely defined. Problems involving generalized anxiety, for example, are unlikely to be alleviated by step-by-step, behaviour-by-behaviour interventions (Wilson, 2011). This failure to address some types of psychological disorders is one of the reasons behavioural interventions are now usually combined with cognitive approaches.

Cognitive-Behavioural Therapies

LEARNING OBJECTIVE 5

Describe cognitive-behavioural therapies for psychological disorders.

Working from the assumption that dysfunctional thinking is at the centre of many psychological disorders, cognitive-behavioural therapists try to help people recognize and change their faulty thinking processes. Because different disorders involve different kinds of cognitive dysfunction, therapists may employ a range of cognitive strategies. Most such therapists also use some behavioural techniques to help clients think, behave, and feel better. Thus, this approach is typically referred to as cognitive-behavioural. Three influential cognitive-behavioural approaches are those of Albert Ellis, Aaron Beck, and the "second-wave" cognitive-behavioural therapists (who use approaches focused on the present; see Cristea et al., 2013).

Ellis's Rational-Emotive Behavioural Therapy

In line with his belief that irrational assumptions give rise to abnormal functioning, Albert Ellis developed an approach called **rational-emotive behavioural therapy** (Ellis, 2013, 2011, 2005, 1962). Therapists using this approach first help clients identify the irrational assumptions that seem to govern their behavioural and emotional responses. Next, they help clients change those assumptions into constructive ways of viewing themselves and the world. One of the techniques the therapists may use is *cognitive restructuring*, in which clients learn to replace negative interpretations with more positive notions (Clark, 2013) (see **Figure 16.5**).

rational-emotive behavioural therapy Ellis's therapy technique designed to help clients discover and change the irrational assumptions that govern their emotions, behaviours, and thinking.

FIGURE 16.5 Cognitive restructuring This cognitive strategy can help clients change self-defeating thinking and, in turn, open the door to new, more positive life experiences.

In his own practice, Ellis would point out to clients their irrational assumptions in a blunt, confrontational, and often humorous way. Then he would model the use of alternative assumptions. After criticizing a young man's perfectionistic standards, for example, he might say, "So what if you did a lousy job on that paper? It's important to realize that one lousy paper simply means one lousy paper, and no more than that!" Ellis gave clients homework assignments requiring them to observe their assumptions at work in their everyday lives. He also required them to think of ways to test the rationality of the assumptions. And, finally, he had them rehearse new assumptions during therapy and apply them at home and work.

Research evaluating the effectiveness of rational-emotive therapy suggests that this form of therapy has been demonstrated to be an effective means of addressing issues for those who suffer from anxiety or assertiveness issues. For example, clients with social anxiety who are treated with this therapy improve more than socially anxious clients who receive no treatment or placebo treatments (Dryden, 2014).

Beck's Cognitive Therapy

Aaron Beck independently developed a system of therapy that is similar to Ellis's rational-emotive behavioural therapy. Although he named his approach **cognitive therapy**, Beck has emphasized for decades that he also has clients experiment with new behaviours as a key feature of the approach.

cognitive therapy Beck's cognitive therapy technique designed to help clients recognize and change their dysfunctional thoughts and ways of thinking.

This approach has been used most often with people who are depressed, although it also has been applied to problems ranging from panic disorder to personality disorders (Beck, Davis, & Freeman, 2015; Milrod et al., 2015; Beck & Weishaar, 2011). In their work with depressed clients, Beck-like cognitive therapists help clients to identify the negative thoughts and errors in logic that pervade their thinking and help give rise to feelings of depression. The therapists also teach clients to challenge their dysfunctional thoughts, try new interpretations, and apply different ways of thinking in their daily lives. In the following excerpt, Beck guides a depressed 26-year-old graduate student to see the link between the way she interprets her experiences and the way she feels, and to begin questioning the accuracy of her interpretations.

Patient: I get depressed when things go wrong. Like when I fail a test.

Therapist: How can failing a test make you depressed?

Patient: Well, if I fail I'll never get into law school.

Therapist: So failing the test means a lot to you. . . . Did everyone who failed get depressed enough to require treatment?

Patient: No, but it depends on how important the test was to the person.

Therapist: Right, and who decides the importance?

Patient: I do . . .

Therapist: Now what did failing mean?

Patient: (Tearful) That I couldn't get into law school.

Therapist: And what does that mean to you?

Patient: That I'm just not smart enough.

Therapist: Anything else?

Patient: That I can never be happy.

Therapist: And how do these thoughts make you feel?

Patient: Very unhappy.

Therapist: So it is the meaning of failing a test that makes you very unhappy. [Moreover] you get yourself into a trap—by definition, failure to get into law school equals "I can never be happy."

(Beck, A. T., Rush, A. J., Shaw, B. F., & Emery, G. (1979). *Cognitive therapy of depression*. New York: Guilford Press, pp. 145–146.)

Around two-thirds of depressed people who are treated with Beck's cognitive approach improve (see photo). This is significantly more than those who receive no treatment and about the same as those who receive biological treatments (Beck & Weishaar, 2011; Disner et al., 2011). Research also indicates the effectiveness of Beck-like cognitive therapy in cases of panic disorder and social anxiety disorder (Jazaieri, Goldin, & Gross, 2016; Milrod et al., 2015).

Depression **Cognitive therapy is effective at identifying the negative thoughts and errors in logic that permeate the thinking of depressed individuals.**

Second-Wave Cognitive-Behavioural Therapies

A growing body of research suggests that the kinds of cognitive changes proposed by Ellis, Beck, and other cognitive therapists are not always possible to achieve (Sharf, 2012). Thus, a new group of cognitive-behavioural therapies, sometimes called *second-wave* cognitive-behavioural therapies, has emerged (Hollon & DiGiuseppe, 2011). These approaches help clients to *accept* many of their problematic thoughts rather than judge them, act on them, or try fruitlessly to change them. The hope is that by recognizing such thoughts for what they are—just thoughts—clients will eventually be able to let them pass through their awareness without being particularly troubled by them.

One of several disorders to which this kind of approach has been applied is generalized anxiety disorder. As you read in Chapter 15, this disorder is characterized by persistent and excessive feelings of anxiety and endless worrying about numerous events and activities. Second-wave cognitive-behavioural therapists guide clients with generalized anxiety disorder to recognize and then accept their dysfunctional uses of worrying (Newman et al., 2011; Ritter, Blackmore, & Heimberg, 2010; Wells, 2010). They begin by educating the clients about the role of worrying in their disorder and have them observe their bodily arousal and cognitive responses across various life situations. Over time, the clients come to appreciate the triggers of their worrying, their misconceptions about worrying, and their misguided efforts to control their lives by worrying. As their insights grow, clients are expected to see the world as less threatening (and so less arousing), try out more constructive ways of dealing with arousal, and, perhaps most important, worry less about the fact that they worry so much. Research has begun to indicate that a concentrated focus on worrying of this kind is indeed a helpful addition to the treatment of generalized anxiety disorder (Bystritsky, Khalsa, Cameron, & Schiffman, 2013; Ritter et al., 2010; Wells, 2010).

Currently, a third wave of cognitive-behavioural approaches focuses on processes associated with health and well-being, such as mindfulness, acceptance, spirituality, and

other ways in which individuals become aware of their thoughts in non-judgmental ways. One example of this, *mindfulness-based cognitive therapy*, developed by psychologist Steven Hayes and his colleagues as part of their broader treatment approach called *acceptance and commitment therapy* (Antony, 2011; Treanor, 2011), helps clients to become mindful of their streams of thoughts—including their worries—at the very moments they are occurring, and to *accept* such thoughts as mere events of the mind. By accepting their thoughts rather than trying to eliminate them, clients are expected to be less upset and affected by them.

Mindfulness-based cognitive therapy has also been applied to psychological problems such as depression, posttraumatic stress disorder, personality disorders, and substance abuse, often with promising results (Johnson et al., 2016; King & Favorite, 2016; Kuyken et al., 2016). The approach borrows heavily from a form of meditation called *mindfulness meditation*, which teaches individuals to pay attention to the thoughts and feelings that flow through their minds during meditation and to accept such thoughts in a non-judgmental way. See Positive Psychology 16.1 for further information on mindfulness and third-wave cognitive behavioural approaches.

Third-Wave Cognitive-Behavioural Therapy

Cognitive behavioural therapies (CBTs) are a group of associated psychotherapies that share a core belief that cognitions and emotions may lead to dysfunctional behaviours. The overall aim of cognitive behavioural therapeutic interventions is to help clients reduce or eliminate undesirable thoughts and emotions.

The "family" of CBTs evolved over time. Behavioural therapy's "first wave" was characterized by applying the traditional concepts of operant and classical conditioning—focusing on changing overt behaviours using basic learning and conditioning paradigms. The "second wave" of CBTs was initiated by psychologists such as Albert Ellis and Aaron Beck, who demonstrated how an individual's internalized (covert) thoughts and beliefs affected their behaviours and emotional experiences.

More recent "third-wave" cognitive behavioural therapies view individuals as capable of growth and change and, rather than treating mental illness or maladaptive behaviour using issue-focused approaches, they value holistic approaches. The idea is that once an individual sees the entire picture of their well-being, they are more likely to stop focusing on a single problem and instead focus on becoming a happier, more well-rounded human being. Therapists help clients to strive for rewarding and healthy mental lives using processes such as mindfulness, metacognition, acceptance, and compassion, and by emphasizing values, comprehensive life goals, and positive emotions. Third-wave approaches help clients to accept their thoughts without judging them as good or bad but to view them only as internal experiences. Evidence-based methodologies such as mindfulness based cognitive therapy, dialectical behaviour therapy, compassion focused therapy, and acceptance and commitment therapy are common approaches used by third-wave clinicians (Micallef-Trigona, 2018). Some

researchers have suggested that practitioners can best serve clients by employing methods from all three CBT waves and methods that are particularly effective with specific client populations (Wolitzky-Taylor, Arch, Rosenfield, & Craske, 2012). Other researchers have argued that the real value of third-wave approaches is their readiness to include aspects of other, less scientifically based approaches, such as psychoanalysis, Gestalt therapy, and humanism (Hayes & Hoffman, 2017).

In a review of the development of cognitive therapies for depression and the effectiveness of different approaches, Keith Dobson (2016), from the University of Calgary, addressed the efficacy of mindfulness as a third-wave therapy for the treatment of depression. Specifically, Dobson addresses the effectiveness of mindfulness based cognitive therapy (MBCT) as an intervention for relapse prevention. He argues that a basic assumption of MBCT is that depressed individuals respond not only to environmental triggers or stressors, but that they also think about, and regulate, thoughts about the depression itself. MBCT helps patients to be mindful (open, flexible, attentive) of these thoughts and to use this awareness as a way of resisting depression. Dobson cites literature acknowledging this approach as effective for patients, especially patients with recurrent depressive episodes, but he also cites research arguing that this approach is not always successful because depressed individuals are sometimes unable to accept negative processing (see Bondolfi et al., 2010). Therefore, Dobson argues that third-wave CBT approaches require further consideration for use with depression.

Cognitive-Behavioural Therapies in Perspective

A model that sees and treats thought as the main cause of normal and abnormal behaviour offers great appeal. Accordingly, therapists from varied backgrounds have come to embrace and use cognitive-behavioural approaches. Moreover, research has supported these approaches. Cognitive-behavioural therapies have proved very effective for treating depression, social anxiety disorder, generalized anxiety disorder, panic disorder, sexual dysfunctions, and a number of other psychological disorders (Beck & Weishaar, 2011).

But the cognitive-behavioural approaches also have their limitations. First, although disturbed cognitive functioning is found in many psychological disorders, its precise role has yet to be determined. It is not always clear that it is at the *centre* of various disorders. Correspondingly, it is not clear whether it is the behavioural or the cognitive features of the cognitive-behavioural approaches that most powerfully propel these treatments. The assumption of many therapists is that the behavioural features help bring about essential cognitive changes. But it could well be that in many cases and disorders, it is the behavioural changes that are most important. And, finally, although cognitive-behavioural therapies are certainly effective for many problems, they do not help everyone (Sharf, 2012).

What Do You Think? • We all sometimes have irrational assumptions, though they don't usually cause psychological disorders. What irrational assumptions and thoughts do you occasionally have?

Humanistic and Existential Therapies

LEARNING OBJECTIVE 6

Describe the humanistic and existential therapies for psychological disorders.

Believing that psychological disorders are rooted in self-deceit, humanistic and existential therapists try to help clients look at themselves and their situations more accurately and acceptingly. They expect that clients will then be better able to actualize their full potential as human beings. To achieve this, humanistic and existential therapists usually emphasize present experiences rather than events from the client's past (Krug, 2019).

Rogers's Client-Centred Therapy

Clinicians who practise Carl Rogers's **client-centred therapy** try to create a positive climate in which clients can look at themselves honestly and acceptingly (Raskin et al., 2011). The therapist must display three important qualities throughout the therapy:

Unconditional positive regard—full and warm acceptance for the client.

Accurate empathy—skillful listening, including restatements of the client's own comments.

Genuineness—realness, sincere communication, no professional front or facade.

client-centred therapy humanistic therapy designed to help clients experience unconditional positive regard and look at themselves honestly and acceptingly.

According to Rogers, clients will feel accepted by their therapists in this kind of atmosphere. They will eventually come to recognize and value their own emotions, thoughts, and behaviours once again. They will then be freed from the insecurities that have been preventing self-actualization (Rogers, 1980). The following interaction shows a therapist using the techniques Rogers advocates:

Client: In classes I feel that everyone's just waiting for a chance to jump on me. . .. When I meet somebody I wonder what he's actually thinking of me. Then later on I wonder how I match up to what he's come to think of me.

Therapist: You feel that you're pretty responsive to the opinions of other people.

Client: Yes, but it's things that shouldn't worry me.

Therapist: You feel that it's the sort of thing that shouldn't be upsetting, but they do get you pretty much worried anyway.

Client: . . . There are lots of little things that aren't true. . . . Things just seem to be piling up, piling up inside of me. . . . It's a feeling that things were crowding up and they were going to burst.

Therapist: You feel that it's a sort of oppression with some frustration and that things are just unmanageable.

Client: In a way . . . . I'm afraid I'm not very clear here but that's the way it comes.

Therapist: That's all right. You say just what you think.

(Snyder, W. V. (1947). *Casebook of non-directive counseling*. Boston: Houghton Mifflin, pp. 2–4.)

iofoto/Shutterstock.com

An alternative source of unconditional positive regard **Based on the Rogerian principle that unconditional positive regard is highly therapeutic, pet therapy has become a widely applied intervention to help reduce the depression of people such as elderly nursing home residents. In this approach, individuals interact with various kinds of non-judgmental animals.**

Rogers was committed to clinical research, and his commitment helped promote the systematic study of treatment. There is not a great deal of research evidence for the efficacy of client-centred therapy; however, the core practices employed in client-centred therapy do have research support (Hoffman et al., 2016). Although some studies report improvements among people who receive this therapy, most controlled research finds it to be of limited effectiveness. Nevertheless, Rogers's therapy has had a very positive influence on the clinical field (Raskin et al., 2011). As one of the first major alternatives to psychodynamic therapy, it helped open up the field to new approaches (Miller, 2014) (see photo).

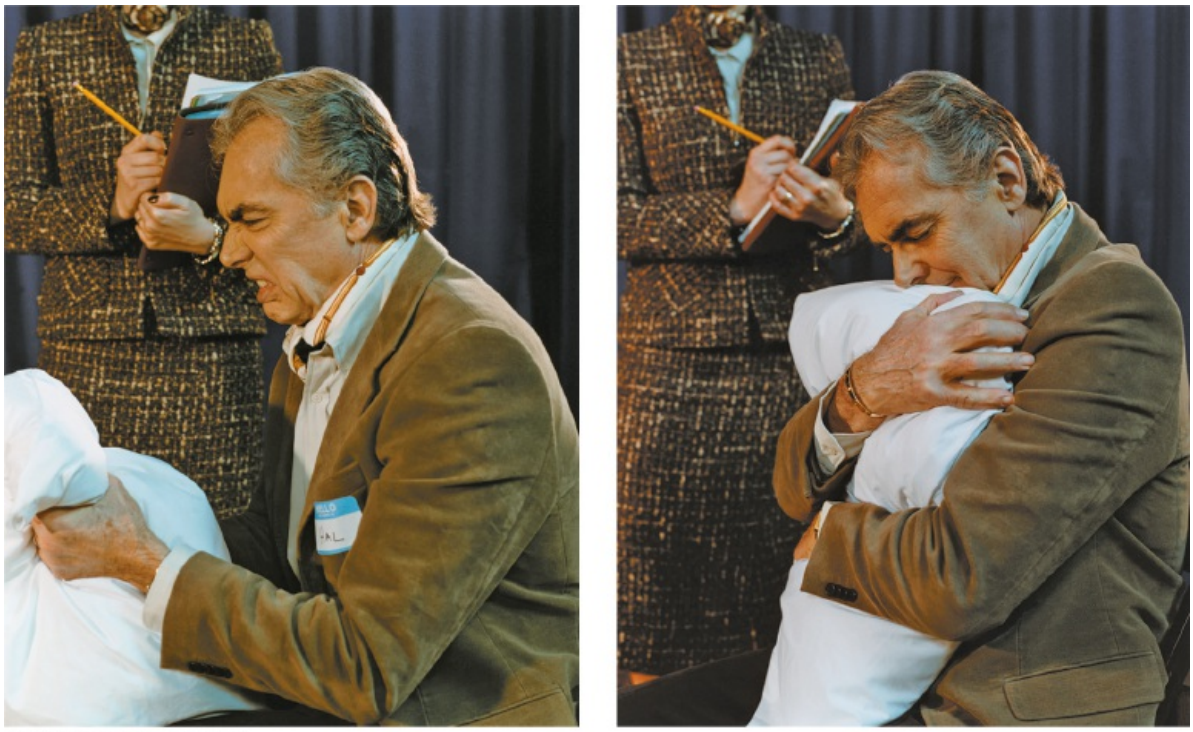
Gestalt Therapy

Gestalt therapy, another humanistic approach, was developed in the 1950s by clinical

theorist Frederick (Fritz) Perls. Gestalt therapists, like client-centred therapists, move clients toward self-recognition and self-acceptance (Yontef & Jacobs, 2011). But unlike client-centred therapists, they often try to do this by challenging and frustrating the clients. Perls's favourite techniques included skillful frustration, role playing, and rules.

> *Skillful frustration* Gestalt therapists consistently refuse to meet their clients' expectations or demands. The aim here is to help the clients to see how often they try to manipulate others into meeting their needs.
>
> *Role playing* Gestalt therapists often have clients act out various roles. A person may be instructed to be another person, an object, an alternate self, or even a part of the body. Role playing can become very intense, as individuals are encouraged to fully express their feelings. They may cry out, scream, kick, or pound. Eventually they are expected to "own," or accept, feelings that previously made them uncomfortable.
>
> *Rules* The rules enforced by Gestalt therapists ensure that clients look at themselves closely. In certain versions of this therapy, for example, clients may be required to use "I" language instead of "it" language. They must say, "I am sad" rather than "The situation is depressing."

Because Gestalt therapists believe that subjective experiences and self-awareness defy objective measurement, limited research has been conducted on the approach (Yontef & Jacobs, 2011). Recently, Gestalt techniques have been included in a group of other treatments referred to as *emotion-focused*. These treatments emphasize attention to one's current emotional experiences as a way to reduce anxiety, depression, and other psychological difficulties (Goldman, 2016) (see photos).



Pascal Preti/Getty Images

Gestalt techniques **Gestalt therapists often guide clients, such as this man, to**

express their needs and feelings to an extreme through role playing and other exercises. In this session, the client moves from "strangling" a pillow (left), to banging the pillow, to hugging it (right). The pillow may represent a person about whom the client has mixed feelings.

Existential Therapy

Existential therapists encourage clients to accept responsibility for their lives and their problems. They help clients to recognize their freedom so that they may choose different paths and live more meaningful lives (Yalom & Josselson, 2011; Schneider & Krug, 2010). Existential therapists also place great emphasis on the relationship between therapist and client, and try to create an atmosphere of honesty, shared learning, and growth.

Like Gestalt therapists, most existential therapists do not believe that experimental methods can properly test the effectiveness of their treatments (Yalom & Josselson, 2011). In fact, they hold that research dehumanizes individuals by reducing them to test measures. Thus, little controlled research has been done to clarify the effectiveness of this approach.

Humanistic and Existential Therapies in Perspective

By recognizing the special challenges of human existence, both humanistic and existential therapists highlight an aspect of psychological life that is typically missing from the other models (Watson, Goldman, & Greenberg, 2011). In addition, the factors that they say are critical to positive functioning—self-acceptance, personal values, personal meaning, and personal choice—certainly seem to be lacking in many people with psychological disorders. Such virtues aside, the broad issues of human fulfillment at the core of these approaches are hard to research. Only recently have properly controlled studies been conducted. These studies, in fact, suggest that the therapies may be beneficial in some cases (Hoffman et al., 2019; Krug, 2019; Schneider & Krug, 2010). This emerging interest in research regarding humanistic and existential therapies may soon lead to clearer insights about these approaches. Positive Psychology 16.2 shows how humanistic and existential psychology share similar understandings of concepts such as well-being and self-actualization with positive psychology.

16.2 Psychology Around Us | Positive Psychology

Instilling Well-Being in Culturally Diverse University Students

A variety of validated interventions targeted at helping students to flourish in academic settings have been developed (Kern, Waters, Adler, & White, 2015; White & Waters, 2015), but they are rarely used in post-secondary institutions. To help change that, Louise Lambert at the Canadian University in Dubai and colleagues from Canada and South Korea (Lambert, Passmore, & Joshanloo, 2019) introduced a 14-week positive psychology intervention happiness program to university students from 39 different nations, all studying in the United Arab Emirates. Positive psychology interventions are empirically validated activities aimed at increasing positive emotions and at facilitating positive thoughts, leading to well-being, and decreasing depressive and anxious symptoms (Weiss, Westerhof, & Bohlmeijer, 2016). Lambert and

colleagues deliberately chose happiness as a variable of well-being in their program. Happiness is not universally viewed as desirable across all cultures and religions. Fear of happiness, the fragility of happiness, or happiness acting as an invitation to future negative consequences exist across many cultures (Joshanloo et al., 2014; Joshanloo, 2013).

Lambert et al.'s study (2019) was aimed at evaluating changes in well-being in a culturally diverse group of students after they completed a one-semester happiness program, Happiness 101, and assessing the program's impact on feelings regarding the fragility of happiness. The Happiness 101 program was based on the PERMA model (Seligman, 2011) that offers five pathways to well-being: Positive emotion, Engagement, Relationships, Meaning, and Accomplishments. Results indicated that students benefited from the program's positive psychological interventions and showed increased *hedonic* (pleasure and enjoyment) and *eudaimonic* (finding meaning and purpose in life) well-being from pre- to post-testing. Increases in well-being were at high levels when measured three months post follow-up. Results also indicated that engaging in the intervention, learning about the science of well-being, and being exposed to positive psychological concepts served to reduce beliefs regarding the fear of happiness and the fragility of happiness. This reduction in fear in turn reduced pessimistic thinking in participants. No significant differences due to religion or faith were observed across participants. The authors indicate that their results argue for the importance of tracking indicators in the well-being of students.

What Do You Think? • What kind of clients and what kind of problems do you think would benefit most from humanistic and existential therapies?

Formats of Therapy

LEARNING OBJECTIVE 7

Describe commonly used formats of therapy.

Thus far, our discussions of therapy have centred on treatments conducted by individual therapists with individual clients. In fact, **individual therapy** is the oldest of the modern therapy formats. Other formats, often used as alternatives to individual therapy, include *group therapy,* (Fonagy, Campbell, & Bateman, 2017) *family and couple therapy* (McGoldrick & Hardy, 2019), and *community treatment* (see photos). Therapists may apply their favoured techniques and principles in each of these formats, whether psychodynamic, behavioural, or other techniques. In addition, special strategies have been developed for use in the non-individual formats.

individual therapy psychotherapy format in which the therapist sees the client alone; the oldest of the modern formats.

Wavebreakmedia/Getty Images

monkeybusinessimages/Getty Images

lightfieldstudios/123 RF

Range of formats Individual therapy (left) used to be the only treatment format for psychological problems. Today, other formats are also used, such as group therapy

(middle) and couple therapy (right).

Group Therapy

In **group therapy**, a therapist sees several clients who are grappling with psychological problems at the same time. Group therapy became a popular format for treating people with psychological difficulties after World War II, when growing demand for psychological services forced therapists throughout North America and Europe to look for time-saving alternatives to individual therapy (Fehr, 2014). Many therapists now specialize in group therapy, and others conduct therapy groups as one aspect of their practice.

> **group therapy** psychotherapy format in which a therapist sees several clients at the same time.

Typically, group members meet with a therapist and discuss the problems or concerns of one or more of the members (Burlingame & Baldwin, 2011). Groups are often created with particular client populations in mind. For example, there are groups for people with alcoholism, for people who are physically handicapped, and for people who are divorced, abused, or bereaved.

On the basis of his own work and other investigations, a leading group-therapy theorist, Irvin Yalom, suggests that successful forms of group therapy share certain "curative" features (Yalom & Leszcz, 2014):

> *Guidance* Group therapy usually provides information and advice for members.
>
> *Identification* Group therapy provides models of appropriate behaviour.
>
> *Group cohesiveness* Group therapy offers an atmosphere of solidarity in which members can learn to take risks and accept criticism.
>
> *Universality* Members discover that other people have similar problems.
>
> *Altruism* Members develop feelings of self-worth by helping others.
>
> *Catharsis* Members develop more understanding of themselves and of others and learn to express their feelings.
>
> *Skill building* Members acquire or improve social skills.

One kind of group intervention in wide use today is **self-help groups**. These groups are made up of people who have similar problems or who may be at different places in a life process (e.g., supporting a loved one with Alzheimer's) and come together to help and support one another without the direct leadership of a professional clinician (White & Madara, 2011). Self-help groups have become increasingly popular over the past few decades.

> **self-help groups** groups consisting of people who have similar problems and come together to help and support one another without the direct leadership of a professional clinician.

Self-help groups address a wide assortment of issues. Examples include alcoholism and

other forms of substance abuse, compulsive gambling, bereavement, overeating, phobias, child abuse, medical illnesses, rape victimization, unemployment, and divorce. Online self-help chat rooms and message boards are often similar to traditional self-help groups and have themselves exploded in number and popularity in recent years.

Self-help groups are popular for several reasons. Many participants have lost confidence in the ability of clinicians and social institutions to help with their particular problems. For example, Alcoholics Anonymous, the well-known network of self-help groups for people dependent on alcohol, was developed in 1934 in response to the general ineffectiveness of clinical treatments for alcoholism (Cheever, 2015). Still other people are drawn to self-help groups because they find them less threatening and less stigmatizing than therapy groups.

Because groups—from conventional therapy groups to self-help groups—vary so much, it has been difficult to assess their effectiveness. Research does suggest, however, that group therapy is often of help to clients—perhaps as helpful as individual therapy (Cruwys et al., 2015; Burlingame & Baldwin, 2011). It appears that candid feedback is usually useful for group members as long as a balance is struck between positive and critical feedback (Slone et al., 2015).

Family Therapy

Family therapy dates back to the 1950s. In this format, therapists meet with all members of a family, point out problematic behaviours and interactions between the members, and try to help the whole family change (Goldenberg & Goldenberg, 2011) (see photo). Most family therapists meet with family members as a group, but some choose to see them separately. Either way, the family is viewed as the unit under treatment.

> **family therapy** a format in which therapists meet with all members of a family to help the whole family to change.

PokPak05/iStock/Getty Images Plus

Family therapy In family therapy, the family is treated as a unit, regardless of whether individual family members are counselled or whether the entire family is

counselled together.

Like group therapists, family therapists may follow the principles of any of the major theoretical models. Whatever their orientation, however, most also adhere to some of the principles of family systems theory. Family systems theory holds that each family has its own implicit rules, relationship structure, and communication patterns that shape the behaviour of the individual members, including dysfunctional behaviour. For one family member to change, the family system must change (Gurman & Kniskern, 2014).

Family therapies are often helpful to individuals (Blow & Karam, 2016). Research has not fully clarified how helpful, however (Goldenberg & Goldenberg, 2011). Some studies have found that as many as 65 percent of individuals treated with family approaches improve, but other studies have found much lower success rates. Nor has any one type of family therapy emerged as consistently more helpful than the others (Sexton & Lebow, 2015; Carr, 2014).

Couple Therapy

In **couple therapy**, also known as **relationship counselling**, the therapist works with two people who are in a long-term relationship, focusing on the structure and communication patterns in their relationship (Gurman & Snyder, 2011; Baucom et al., 2010). Often this format of therapy involves a husband and wife, but the couple need not be married or even living together. Similarly, they need not be heterosexual. Indeed, some therapists specialize in working with same-sex couples.

> **couple therapy** or **relationship counselling** therapy format in which a therapist works with two people who are in a long-term relationship.

Although some degree of discord occurs in any long-term relationship, there is growing evidence that many adults in our society experience serious relationship issues. Currently, it is estimated that 38 percent of Canadian marriages do not survive past the thirtieth anniversary and over 41 percent do not survive past fifty years of marriage (Statistics Canada 2020; Saint-Jacques et al., 2016; Milan, 2013). Other cohabitation arrangements show similar patterns of dissolution or separation (Bouchard & Saint-Aubin, 2014).

Like group and family therapy, couple therapy may be conducted using any theoretical techniques or perspectives (Baucom et al., 2010). People treated in couple therapy show greater improvements in their relationships than people who fail to receive such treatment. Some research suggests that no one form of couple therapy stands out as more effective than the others (Gurman & Snyder, 2011; Christensen et al., 2010) but other research suggests that emotion-focused therapy is superior to other approaches for couple therapy (Dalgleish et al., 2015; Johnson & Greenberg, 2013). Two-thirds of treated couples display improved marital functioning. However, fewer than half of those who are treated achieve “distress-free” relationships. One-quarter of all treated couples eventually divorce (Hewison, Casey, & Mwamba, 2016; Petch, Lee, Huntingdon, & Murray, 2014).

Community Treatment

At one time, people with psychological disorders, especially severe disorders, had to seek

help from distant facilities or institutions. Today, however, a number of **community mental health treatment** programs offer such people services from nearby agencies. Community-based treatments include community mental health centres, community day programs, and group homes and other residential services. Collectively, these agencies often play a major role in the treatment of people with severe psychological disorders, such as schizophrenia (Daly, Doherty, & Walsh, 2010) (see photo).

community mental health treatment treatment programs that emphasize community care, including an emphasis on prevention.

M. Spencer Green/AP

Community mental health in action **This man diagnosed with both schizophrenia and bipolar disorder is moving into his own apartment, a key step in his recovery.**

A key feature of community treatment is *prevention*. Community clinicians reach out to clients rather than wait for them, an approach that is often very successful (Conyne & Harpine, 2010; Juhnke, Granello, & Granello, 2011). Community workers identify three types of prevention: *primary*, *secondary*, and *tertiary*.

Primary prevention consists of efforts to improve community functioning and policies. The goal of primary prevention is to prevent psychological disorders altogether. Community workers may lobby for better child-care facilities in the community, consult with a district school board to help develop a curriculum, offer mental health fairs or workshops on stress reduction, or provide online information and support sites.

Secondary prevention consists of detecting and treating psychological disorders in the early stages, before they reach serious levels. At the secondary prevention level, community workers may teach clergy, teachers, or police how to identify early signs of psychological dysfunction and how to refer people for treatment.

Tertiary prevention aims to provide effective treatment immediately so that moderate or severe disorders do not become chronic problems. Unfortunately, although

community agencies are able to offer tertiary care for millions of people with moderate problems, low funding often prevents them from providing care for many of the other hundreds of thousands with severe disorders (Althouse, 2010). See Psychology Around Us 16.2 for more information on community care.

16.2 Psychology Around Us

In Need of Comprehensive Community Care

What happens to people with severe psychological disorders whose communities do not provide the mental health services they need and whose families cannot afford private treatment? Many depend on their families and receive medication and support, but little else in the way of treatment (Bucci, Berry, Barrowclough, & Haddock, 2016). Approximately 8 percent receive only custodial care and medication in an alternative institution, such as a nursing home or rest home. As many as 18 percent are placed in privately run residences, such as boarding houses, where supervision often is provided by untrained individuals. Another 31 percent live in totally unsupervised settings, including rundown single-room-occupancy hotels or rooming houses, surviving on government disability payments, and spending their days without purpose (Burns & Drake, 2011). Many become homeless (Kooyman & Walsh, 2011), and many more end up in prisons (Scott, 2010).

With these statistics in mind, Anita Palepu, from the University of British Columbia, and her colleagues investigated the effects of concurrent disorders (defined as co-occurring mental health and substance-related disorders) and health care use in homeless and vulnerably housed single adults from Vancouver, Toronto, and Ottawa over a four-year period (Zhang et al., 2018). In their sample, 44 percent of participants who reported mental health issues also reported substance abuse issues. Individuals with concurrent disorders were more likely to be younger, to be female, to have three or more chronic health issues, and to have a history of incarceration in the previous year. Three out of five participants with concurrent disorders reported polysubstance use, defined as using three or more substances. The study findings indicated that concurrent disorders, homelessness, chronic health conditions, and a history of incarceration were significant predictors of emergency department (acute care) use. Moreover, the level of acute care and primary care utilization was significantly higher among those with concurrent disorders than among those without concurrent disorders. This data supports previous findings indicating that primary care services are unable to effectively manage mental health symptoms and substance use in homeless and vulnerably housed individuals, underscoring the need for more comprehensive programs for such people with mental health and/or substance use disorders.

Does Therapy Work?

LEARNING OBJECTIVE 8

Summarize research on the effectiveness of therapy.

As we noted earlier, as many as 400 forms of therapy are currently practised in North America (Corsini & Wedding, 2011). The most important question to ask about each of them is whether the therapy really helps. **Therapy outcome studies**, which measure the effects of various treatments, typically ask one of four questions:

Is therapy in general effective? Studies reveal that therapy is often more helpful than no treatment or placebo treatments. Using a statistical technique called *meta-analysis* in which the results from a large number of studies are combined to provide a more general picture of a particular area of interest, a variety of studies indicate that psychotherapy across a wide range of disorders is more effective than no treatment at all, for the majority of clients (Swift, Spencer, & Goode, 2018; Campbell et al., 2013; Cuijpers, Berking et al., 2013; Sharf, 2012). However, psychotherapy does not work for everyone, with some clients reporting that they experienced the therapeutic process as distant or artificial or as overly focused on the past (Werbart, Von Below, Brun, & Gunnarsdottir, 2015). Approaches unique to Indigeous people are discussed in Indigenous Experiences 16.2.

How effective are particular therapies? A number of studies have found that each of the major forms of therapy is of some help to clients—certainly of more help than a placebo treatment (Shean, 2016; Huhn et al., 2014; Prochaska & Norcross, 2010; Overholser, Braden, & Fisher, 2010). Other research has compared these major forms of therapy to one another and found that no one form of therapy generally stands out over all others (Miller, Hubble, Chow & Seidel, 2013). Research suggests that different kinds of therapy have similar overall success rates because they share common features such as effectiveness of the therapist, strength of the therapeutic alliance, and the client's role as an active contributor (Owen, Drinane, Idigo, & Valentine, 2015; Sharf, 2012; Bohart & Tallman, 2010). Surveys of highly successful therapists suggest that, regardless of their particular orientations, successful therapists tend to do similar things: (1) they provide feedback to clients; (2) they help clients focus on their own thoughts and behaviour; (3) they pay careful attention to the way they and their clients interact; and (4) they try to build a sense of self-mastery in their clients

(Jennings et al., 2016).

Are particular therapies especially effective for certain problems? Researchers have found that particular therapies are especially effective at treating specific types of disorders (Beutler, 2011; Corsini & Wedding, 2011). Behavioural therapies, for example, seem to be the most effective of all treatments for phobias (Waters, Bradley, & Mogg, 2014; Wilson, 2011). Cognitive-behavioural therapies are particularly helpful in cases of social anxiety disorder, generalized anxiety disorder, panic disorder, and depression (Hudson et al., 2015; Cuijpers, Sijbrandij, et al., 2013; Craske, 2010; Pontoski et al., 2010). And drug therapy is the single most helpful treatment for schizophrenia and bipolar disorder (Minzenberg, Yoon, & Carter, 2011). Today's clinicians may also combine two or more approaches when treating particular disorders (Cuijpers et al., 2010). Drug therapy, for example, is often combined with cognitive-behavioural therapy to treat depression or various anxiety disorders, although the superiority of such combinations over the individual approaches has not been supported consistently by research (Otto, McHugh, & Kantak, 2010; Pontoski & Heimberg, 2010). In fact, it is now common for clients to be seen by two therapists—one of them a physician or psychiatrist who prescribes medication and the other a psychologist, social worker, or other therapist who conducts psychotherapy.

Is therapy equally effective across race and gender? Studies conducted in countries across the world have found that members of ethnic and racial minority groups typically show less improvement in clinical treatment, make less use of mental health services, and stop therapy sooner than members of majority groups (Comas-Diaz, 2011; Benish, Quintana, Wampold, 2011). Given such findings, a number of clinicians have developed **culture-sensitive therapies**, which seek to address the unique issues faced by members of cultural minority groups. Clinicians using these approaches typically try to do the following (Brown, 2011; Comas-Diaz, 2011):

- Be aware of the client's cultural values.
- Be aware of the stress, prejudices, and stereotypes to which minority clients are exposed.
- Be aware of the hardships faced by the children of immigrants.
- Help clients recognize the impact of both their own culture and the dominant culture on their self-views and behaviours.
- Help clients identify and express suppressed anger and pain.
- Help clients achieve a bicultural balance that feels right for them.
- Help clients raise their self-esteem—a sense of self-worth that has often been damaged by generations of negative messages.

therapy outcome studies research that looks at the effects of various treatments.

culture-sensitive therapies approaches that seek to address the unique issues faced by members of cultural minority groups.

16.2 Indigenous Experiences

Healing Journey

Worldviews reflect deeply held values as well as fundamental beliefs about how the world operates, why things happen as they do, and what an individual's purpose is, and they therefore encompass how the world is experienced and understood. The Indigenous worldview includes concepts of holistic and spiritual understanding, a belief in many truths, connection to land, a view of time as nonlinear, and the importance of balance and of relationships with family and community (Castellano, 2006b). It is therefore crucial that effective healing programs for Indigenous people reflect this worldview.

Marlene Brant Castellano a Mohawk, now retired from Trent University, led a team that produced a three-volume report for the Aboriginal Healing Foundation examining the journey to wellness and promising healing practices for addressing the legacy of abuses from the residential school system (2006a; 2006b). Part of the report focused on culturally appropriate ways to address trauma and recovery. Addressing belief systems based on balance, connection, harmony, and growth and recognizing the critical role of identifying with family, ancestors, and community as central to the healing journey for many Indigenous people (2006b). "Principles of 'good' therapy are generally compatible with Aboriginal values, but they tend not to be Aboriginal-specific" (Castellano, 2006a, p. 120).

Based on "lessons from the field, especially the grassroot wisdom of community healing teams who work with these issues everyday" (Castellano, 2006a, p. 121), Castellano and colleagues developed a Framework for Understanding Trauma and Healing Related to Residential School Abuse for developing successful programs with survivors. The framework includes three necessary elements: Indigenous values and worldview, personal cultural safety, and capacity to heal. Further, the framework rests on three pillars of healing: Reclaiming history, cultural interventions, and therapeutic healing. Situated below the three pillars are factors unique to a person such as personal, family, and community history.

Examples of two effective programs cited in the report (Castellano, 2006a) are:

> **Qu'Appelle Child and Family Services (QCFS), Fort Qu'Appelle, Saskatchewan:** QCFS Elders and traditional resource people work with project field staff and residential school survivors from the Muscowpetung, Nekaneet, Pasqua, Piapot, Standing Buffalo, and Wood Mountains First Nations on topics such as "self-esteem, grief, loss, denial, anxiety, guilt and memory" (p. 175). Elders are involved in every aspect of the program and speak in their own language (Dakota, Lakota, Nakota, Ojibway, and Cree); staff speak in English and a project coordinator puts English words into First Nations concepts.
>
> **Centre for Indigenous Sovereignty, *I da wa da di*, Six Nations, Ontario:** I da wa da di (We Should All Speak) offers retreats and workshops open to all Indigenous women in Ontario and also offers training for others who work with survivors. The program blends cultural and traditional elements in an atmosphere described

as "holistically safe, caring, and nonjudgmental" (p. 177). Participants ascribe feelings of safety to factors such as the opportunity to be with Elders, cultural aspects of the program, including traditional teaching, certainty around confidentiality, support from others, and "the presence of love, nurturing and laughter" (p. 177). Program activities are frequently facilitated by past participants, themselves survivors of residential schools and intergenerational trauma.

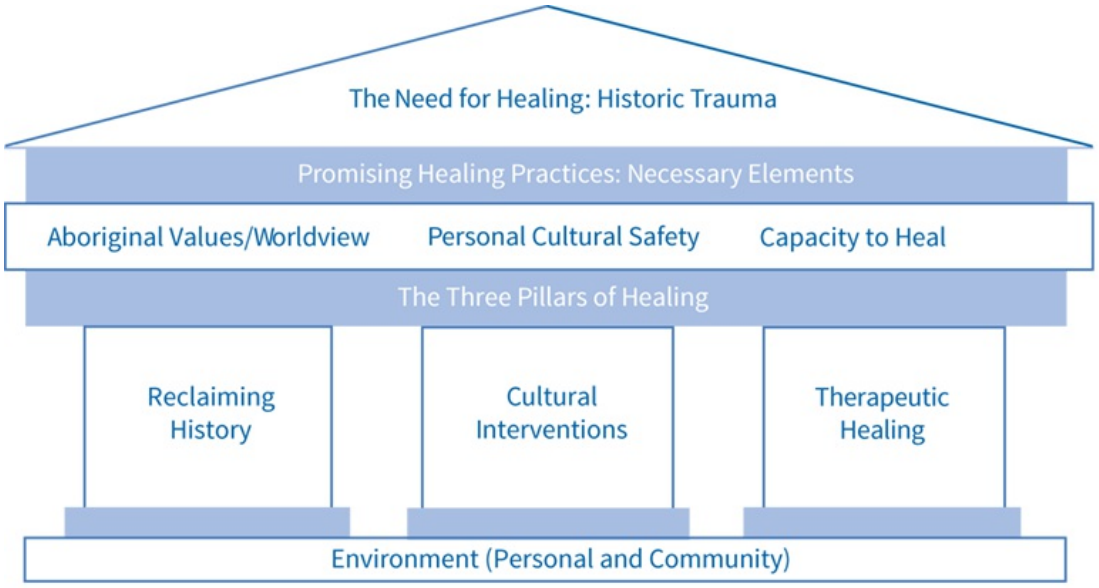
Many other programs are also highlighted in the report, but all share the common features of "two-eyed seeing" as first identified by Mi'kmaw elders Albert Marshall and Murdena Marshall (Marsh et al., 2015; Bartlett et al., 2012; Castellano, 2006b).

The Framework for Understanding Trauma and Healing Related to Residential School Abuse is based on historic trauma theory. It is composed of program elements necessary for supporting the healing process and intervention strategies, the three pillars of healing, necessary for implementing healing processes. In their personal and collective journey, participants can move among the intervention strategies singly or in concert. Below the three pillars of healing are the factors unique to a given individual.

Critical Thinking Questions

Identify culturally appropriate ways that each of the two effective programs identified here address trauma and recovery.

Based on all you have learned about Indigenous experiences, why do you think that Reclaiming History is one of the Three Pillars of Healing in this model?



Source: Marlene Brant Castellano 2006, Final Report of the Aboriginal Healing Foundation A Healing Journey: Reclaiming Wellness, Volume I.

Therapies geared to the pressures of being female, called **gender-sensitive**—or **feminist**

—therapies, follow similar principles (Calogero, Tantleff-Dunn, & Thompson, 2011). In a related vein, when working with clients with spiritual beliefs, many of today's therapists make a point of including spiritual issues in therapy (Aten, McMinn, & Worthington, 2011; Worthington, 2011). These therapists may, for example, encourage clients to use their spiritual resources to help them cope (Galanter, 2010a, 2010b).

> **gender-sensitive** or **feminist therapies** approaches that seek to address the unique pressures of being female.

Obviously, knowledge of how effective particular therapies are for particular disorders and particular populations helps therapists and clients alike to make better decisions about treatment (Beutler, 2011; Beutler et al., 2013) (see Practically Speaking 16.1). To help clinicians become more familiar with and apply such research findings, there is a movement in Canada, the United States, the United Kingdom, and elsewhere called the **empirically supported** or **evidence-based treatment movement** (Norcross & Lambert, 2019; Laska et al., 2014; Sharf, 2012; Pope & Wedding, 2011. This empirically supported treatment movement has been gaining momentum in recent years. Proponents of this movement have formed task forces that seek to identify which therapies have received clear research support for particular disorders, to propose corresponding treatment guidelines, and to share this information with clinicians. Critics of the movement suggest that such efforts are at times simplistic, biased, and even misleading and might benefit from integration with other approaches (Laska et al., 2014).

> **empirically supported** or **evidence-based treatment movement** movement to help clinicians become more familiar with and apply research findings concerning the effectiveness of particular treatments.

Another movement that has been receiving support in recent years is a move toward integration and eclecticism among psychotherapeutic approaches. This move supports the integration of a variety of psychotherapeutic perspectives rather than adherence to a particular orientation. This movement encourages practitioners to integrate diverse approaches and to draw on a variety of perspectives when treating clients. (See the Society for the Exploration of Psychotherapy Integration for more information on this topic.)

16.1 Practically Speaking

How Do I Find and Choose a Therapist?

Selecting the right therapist is obviously a very important decision. Even if you seek assistance at the student wellness or counselling centre at your college or university (where treatment is usually free to students) or if you seek a referral to a therapist from your family doctor, a friend or relatives, or your province's College of Psychologists, you still have some choice regarding which of the available therapists you can work with.

wavebreakmedia/Shutterstock.com

Here is a list of key questions to consider when selecting a therapist. You should direct some of the questions to the potential therapists themselves.

Where can you get names of skilled potential therapists? Ask a professional whom you trust—a psychologist you know, such as your introductory psychology professor, someone at your local student wellness or counselling centre, a family physician, or look on the Internet—for recommendations. Many provinces or cities also provide relevant information and lists.

What is the professional status of the potential therapists? Are they clinical psychologists, psychiatrists, social workers, or counsellors? Are they chartered/registered with your province's regulatory college for their profession?

What is the experience level of the potential therapists? What is their overall experience in the field? What is their specific experience and success rate with your kind of problem?

What is the treatment orientation of the potential therapists? Are they psychodynamic, behavioural, cognitive, humanistic, existential, or eclectic? How do they approach problems such as yours? Does this approach feel like a reasonable fit for you?

What is the success rate of their treatment orientation for problems such as yours? Reading this chapter or an abnormal psychology textbook should help you with this question.

Do the potential therapists believe in psychotropic medication as part of therapy in certain cases? Can they arrange for medication consults with a physician or a psychiatrist if needed?

How do the potential therapists match up on personal variables that are important to you? Access feedback from previous clients. What are their genders, ages, personalities, and the like? Although such factors do not necessarily affect a therapist's ability to help, you may personally feel that the variables could affect your comfort level or confidence in the therapy process.

Once you are in therapy, are you comfortable with the way things are going? Does the therapist seem attentive, interested, and engaged? Does the therapist's approach continue to make sense to you? Do you feel you are making progress? Don't be afraid to change therapists if, after a reasonable period of time, you are not making progress. In most such instances, you are not failing at therapy. The therapy is failing you!

Before You Go On

(Answers to Before You Go On may be found online in the Course Resources.)

What Do You Know?

20. What does research show about whether or not therapy is generally effective?

21. What do effective therapists have in common?

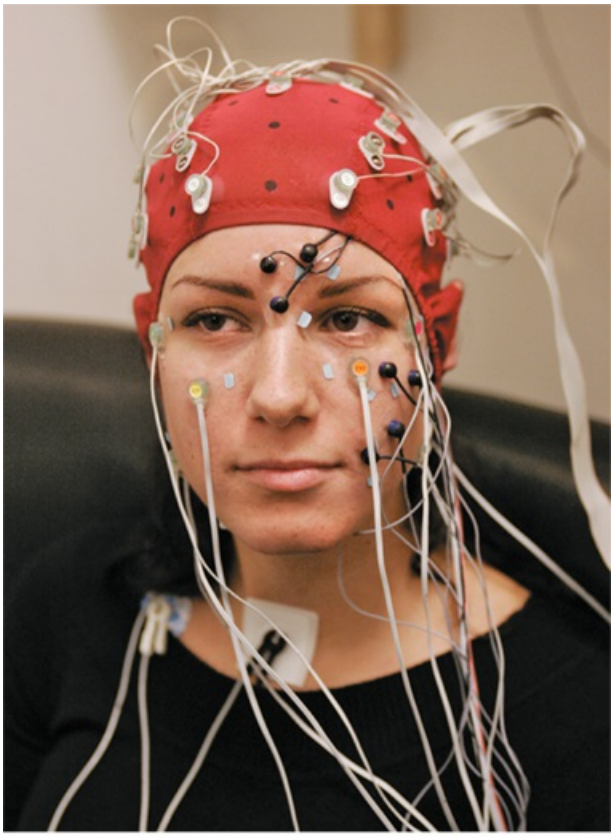
22. What does research show about the effectiveness of particular therapies for certain problems?

23. Is therapy equally effective across race and gender?

What Do You Think? • If a person feels that her treatment is not helping, is it likely worthwhile for that person to try to change therapists or treatment methods? Why or why not?

Some Final Thoughts About the Field of Psychology

It is ironic that we end this book with chapters on abnormal psychology and its treatments. Early on, we noted that many people automatically think of abnormal psychology when they hear the term *psychology*. But, as you have seen throughout this book, psychology is a broad field that studies all kinds of mental processes and behaviour. And, as you have also observed, all of those processes and behaviours—both normal and abnormal—are rather awe-inspiring. For example, disorders of memory, such as Alzheimer's disease and dissociative identity disorder, are certainly fascinating. But normal acts of memory—our very ability to encode, store, and retrieve so many experiences and pieces of information in the first place—are no less remarkable.



Chuck Stoody/AP

Covering all the angles To fully understand a mental process such as "intruding thoughts," today's psychologists study the phenomenon at many levels, from measuring the brain waves of individuals while their minds wander (seen here), to determining the possible childhood roots of such thoughts.

Psychology is a wide-ranging and complex field consisting of many sub-areas, from sensation and perception to social psychology. Each seeks to explain particular aspects of mental functioning from a particular angle. Collectively, these many sub-areas provide us with an impressive understanding of mental processes and behaviour. But it is important to recognize that this understanding is at a very early stage of development. There are many miles to go in our quest to more fully understand the subject matter of psychology.

Perhaps the most important feature of psychological study today—and one that offers enormous promise for the future—is that the sub-areas are coming together. More and more, they are being viewed as closely connected areas of study. Each helps to inform the others, and all can, collectively, provide a more integrated, complete, and accurate understanding of mental processes and behaviour (see photo). It is, for example, no longer a matter of choosing between neuroscience, cognitive psychology, and social psychology to understand how and why people behave (or don't behave) when passing by an accident scene. Rather, we seek to understand how these interacting subfields jointly account for that behaviour. In short, psychology is becoming a truly integrated field. Given this critical course correction, one can only imagine how many insights and breakthroughs regarding mental processes and behaviour lie ahead.

Summary

Treatment in Today's World

LEARNING OBJECTIVE 1 Explain who receives treatment for psychological problems today, how they enter treatment, and what general features characterize different types of treatment.

More than 20 million North Americans receive therapy for psychological problems in the course of a year. Almost half suffer from anxiety and depression.

Therapy was once primarily a privilege of the wealthy, but today people at all socio-economic levels receive treatment. Similarly, while women once outnumbered men in therapy by four to one, men today are more willing to enter therapy than before.

People may enter therapy on their own or may be forced into treatment. Many never seek treatment at all.

A variety of professionals conduct therapy, including psychologists, psychiatrists, counsellors, and psychiatric social workers.

Most clients are treated in the community as out-patients, but some people with severe problems are treated as in-patients in private or public institutions.

All forms of therapy have three essential features: a sufferer who seeks relief, a trained healer, and a series of contacts between the two in which the healer tries to bring about changes in the sufferer's emotional state, attitudes, and behaviour.

Biological Treatments

LEARNING OBJECTIVE 2 Describe the major biological treatments for psychological disorders.

Drug therapy, *electroconvulsive therapy (ECT)*, and *psychosurgery* are the three major categories of biological treatments.

Psychotropic drugs, including *antianxiety, antidepressant*, and *antipsychotic drugs*, have brought relief to many, but they do not work for everyone and may have undesired side effects.

Electroconvulsive therapy (ECT), used primarily to treat depression, is administered less often today than in the past. Two more recently developed brain stimulation treatments, *vagus nerve stimulation* and *transcranial magnetic stimulation*, have fewer wide-ranging and traumatic side effects than ECT.

Psychosurgery today is much more precise than the lobotomies of the past, in which the connections between the frontal lobe and the lower brain centres were severed.

Biological treatments for psychological disorders, particularly drug treatments, are highly regarded today. However, more often than not, biological interventions alone are not enough.

Psychodynamic Therapies

LEARNING OBJECTIVE 3 Describe the psychodynamic treatments for psychological disorders.

Psychodynamic therapies range from classical *Freudian psychoanalysis* to modern therapies. All share the goals of helping clients to uncover past traumatic events and the inner conflicts that have resulted from them, and to resolve those conflicts.

Psychodynamic therapy techniques include *free association*; therapist interpretation of *resistance*, *transference*, and *dreams*; *catharsis*; and repeatedly *working through* issues.

Recent developments in psychodynamic therapy include *short-term psychodynamic therapy* and *relational psychoanalytic therapy*.

The psychodynamic approach has had a lasting influence on the conduct of treatment and was the first to offer an alternative to biological explanations of abnormal functioning. But the effectiveness of psychodynamic therapy is not well supported by research.

Behavioural Therapies

LEARNING OBJECTIVE 4 Describe the behavioural treatments for psychological disorders.

Behavioural treatments, aimed at replacing abnormal behaviours with more functional ones, are based on learning processes. Behavioural techniques fall into three categories: *classical conditioning*, *operant conditioning*, and *modelling*.

Systematic desensitization and *aversion therapy* rely on classical conditioning. Systematic desensitization is especially effective in treating phobias, while aversion therapy has been used to treat people who want to eliminate problem behaviours, such as drinking.

Token economies follow the principles of operant conditioning and use rewards to encourage desired behaviours.

Social-skills training uses modelling to help clients acquire desired social behaviours.

Research suggests that behavioural therapies are often effective. They do not always bring lasting change outside therapy, however, and do not appear particularly effective with disorders that are broad or vaguely defined.

Cognitive-Behavioural Therapies

LEARNING OBJECTIVE 5 Describe cognitive-behavioural therapies for psychological disorders.

Cognitive-behavioural therapists try to help people recognize and change their faulty thinking processes. Most such therapies use some behavioural techniques. Three influential cognitive-behavioural approaches are those of *Albert Ellis*, *Aaron Beck*, and the "*second-wave*" *cognitive-behavioural therapists*.

Ellis's *rational-emotive behavioural therapy* focuses on helping clients to identify their maladaptive assumptions, test them, and change them.

Beck's cognitive therapy guides clients to challenge their maladaptive attitudes,

automatic thoughts, and illogical thinking. Research supports the effectiveness of cognitive therapy for depression and certain other disorders.

Second-wave cognitive-behavioural therapies help clients to accept their problem behaviours rather than judge them, act on them, or try fruitlessly to change them.

The cognitive view is quite popular today, and research suggests that cognitive treatment is often effective. It is still not clear, however, whether psychological disorders create or result from maladaptive thoughts.

Humanistic and Existential Therapies

LEARNING OBJECTIVE 6 Describe the humanistic and existential therapies for psychological disorders.

Humanistic and existential therapists try to help clients look at themselves and their situations more accurately and acceptingly.

Therapists practising Carl Rogers's *client-centred therapy* try to provide *unconditional positive regard*, *accurate empathy*, and *genuineness*, so that clients come to value their own emotions, thoughts, and behaviours.

Gestalt therapists use skillful frustration, role playing, and rules to help clients recognize and accept their needs and goals.

Existentialist therapies focus on helping clients discover their personal freedom of choice and take responsibility for making choices.

Only recently have humanistic and existential therapies begun to undergo systematic research. Early research suggests they can be beneficial for some clients.

Formats of Therapy

LEARNING OBJECTIVE 7 Describe commonly used formats of therapy.

Individual therapy, in which practitioners meet with one client at a time, is the oldest of the modern therapy formats.

In *group therapy*, several clients with similar problems meet with a single therapist at the same time. *Self-help groups* are similar, but conducted without the leadership of a therapist. Both types of groups can be helpful for certain clients.

Family therapy treats all members of a family, together or individually, and therapists usually consider the family as a system.

Two people in a long-term relationship can seek *couple therapy* to help address issues in their relationship.

Community mental health treatment focuses on preventing abnormal functioning through: (1) primary prevention—policies that reduce psychological risk in a community; (2) secondary prevention—treating minor problems before they become serious; and (3) tertiary prevention—providing prompt treatment for moderate and severe disorders so they do not become long-term problems.

Does Therapy Work?

LEARNING OBJECTIVE 8 Summarize research on the effectiveness of therapy.

In general, receiving therapy is more likely to help people with psychological disorders than going without treatment. Research has found that each of the major forms of therapy is of some help to clients, although research also indicates that particular therapies are often best suited for certain disorders.

Successful therapists often share similar effective elements in their approaches, regardless of their particular orientations. They provide feedback, help clients focus on their own thoughts and behaviour, pay careful attention to the way they interact with clients, and try to build a sense of self-mastery in their clients.

Women and members of ethnic minority groups face pressures that sometimes contribute to psychological dysfunctioning. *Culture-sensitive* and *gender-sensitive therapy* approaches help clients become aware of and react adaptively to the gender-related and cultural pressures and issues they face.

The *empirically supported* or *evidence-based treatment movement* seeks to identify which therapies have received clear research support for particular disorders, to propose corresponding treatment guidelines, and to spread such information to clinicians.

Self-Study Questions

Multiple Choice

1. The most common psychological problems that lead people in Canada to seek treatment are

- **a.** anxiety and depression.
- **b.** bipolar disorder and schizophrenia.
- **c.** dissociative disorder and depression.
- **d.** schizophrenia and anxiety.

2. The most commonly used biological treatment for psychological disorders is

- **a.** deep brain stimulation.

b. drug therapy.

c. electroconvulsive therapy.

d. psychosurgery.

3. A client in therapy is asked to describe thoughts as they come to mind. What therapeutic technique does this describe?

a. Free association

b. Resistance

c. Transference

d. Working through

4. The behavioural therapy of systematic desensitization works primarily through the principle of

a. extinction.

b. negative reinforcement.

c. positive reinforcement.

d. punishment.

5. When therapists demonstrate appropriate behaviour to clients and then ask the clients to imitate and rehearse it, this is called

a. a token economy.

b. classical conditioning.

c. modelling.

d. social skills training.

6. Which of the following theorists would be most likely to give clients homework assignments requiring them to observe and challenge their assumptions?

a. Beck

b. Ellis

c. Perls

d. Rogers

7. Which statement about the cognitive-behavioural approach to therapy is false?

a. It has been found to be highly effective.

b. It is difficult to determine whether irrational thoughts are a cause or an effect of maladaptive behaviour.

c. It is only applicable to the treatment of depression and has limited use for other conditions.

d. Research has consistently found that there is a link between maladaptive thoughts and maladaptive behaviour.

8. The Gestalt approach to therapy was developed by

a. Abraham Maslow.

b. Albert Ellis.

c. Carl Rogers.

d. Fritz Perls.

9. A school district launching a smoking awareness program to try to reduce the number of students who start smoking is an example of _____ prevention.

a. educational

b. primary

c. secondary

d. tertiary

10. Research shows that effective therapists tend to do all of the following except

a. encourage clients to focus on their own thoughts and behaviour.

b. pay attention to the interactions between therapist and client.

c. provide feedback to clients.

d. use psychodynamic techniques such as free association and dream analysis.

Fill-in-the-Blank

1. Most people seeking mental health services receive _____ treatment, whereby clients visit a therapist's office, but live in the community.

2. Recent research shows that electroconvulsive therapy (ECT) helps about _____ percent of depressed patients who try it.

3. One downside of _____ medications used to treat disorders such as schizophrenia is that they can cause severe shaking and contractions of the face and body.

4. In psychodynamic therapy, dream interpretation involves examining both the _____ content (the consciously remembered details) and the _____ content (the symbolic meaning of those details).

5. Despite limited evidence of its effectiveness, the psychodynamic approach to therapy is practised by about _____ percent of clinical psychologists.

6. Pointing out the social deficits of clients, then role playing more effective strategies in imaginary social situations, is an approach used in _____ training.

7. Beck's approach to cognitive therapy is most commonly used to treat _____.

8. In contrast to psychodynamic therapy approaches, humanistic and existential therapies usually emphasize _____ experiences rather than conflicts from childhood.

9. One reason why group therapies are helpful is because they encourage group _____, or a sense of unity among group members.

10. Although all forms of therapy tend to help people, some approaches are better suited to particular problems than others. Phobias, for example, are most effectively treated with _____ therapy.

APPENDIX A
Answers to Self-Study Questions

Chapter 1

Multiple Choice 1d, 2d, 3c, 4c, 5a, 6c, 7c, 8c, 9a, 10a. **Fill-in-the-Blank** 1. behaviour 2. control 3. myths 4. functionalists 5. perception 6. punishment 7. self-actualization 8. evolutionary psychology 9. clinical or counselling 10. positive

APPENDIX B
Statistics in Psychology

As outlined in Chapter 2, psychology is considered to be a science, given that it relies upon empirical observations of mental processes and behaviour in order to develop and test theories regarding the underlying laws that govern behaviour. Psychologists use statistics to help them summarize and interpret the observations (or data) that they collect in their research. Essentially there are two basic types of statistics used by psychologists: **descriptive statistics**, which include a variety of procedures used to describe and summarize the data collected, and **inferential statistics**, which are procedures that allow psychologists to draw conclusions about the data they have collected. This appendix is designed to help you better understand statistics and how psychologists use them.

descriptive statistics statistics used to describe and summarize data.

inferential statistics statistics used to draw conclusions about research data.

Descriptive Statistics

Statistics are commonly used in psychology to summarize data that have been collected as part of some research project or study. Such statistical summaries are referred to as descriptive statistics.

To illustrate some common descriptive techniques, consider the following data set:

46	56	50	50	59	44
61	49	50	52	32	43
67	58	51	36	58	46
51	54	53	62	50	39
42	44	51	41	53	57

Assume that the data represent scores obtained from 30 students who have taken their first test in an introductory psychology course.

If the instructor is interested in determining how well the students performed on this test, she might quickly eyeball the scores above. However, nothing may readily jump out at her in terms of things like how well the typical student is doing, what was the lowest score, what was the highest score, and so on.

One of the first things the instructor might want to do to get an idea of what's going on with student performance is to simply sort the data so that the scores are arranged from lowest to highest. Doing so produces a data set like the one in **Table B.1**. Now the instructor can look at the data set to see things like the lowest score earned by a student was 32, a fairly large number of students received scores of 50 and 51, and the highest score earned by a student was 67.

TABLE B.1					
Thirty Exam Scores—Sorted					
32	36	39	41	42	43
44	44	46	46	49	50
50	50	50	51	51	51
52	53	53	54	56	57
58	58	59	61	62	67

However, this still doesn't tell her a whole lot about her students' performance. To get a better idea of what's going on in this set of data, the instructor might use a number of descriptive techniques to summarize the data (this would especially be the case if there were a larger number of students in the class, such as 500). One common way to summarize such a data set is to create frequency distributions.

Frequency Distributions

There are two major types of frequency distributions: ungrouped frequency distributions and grouped frequency distributions. With an **ungrouped frequency distribution**, the number of times that each of the unique scores occurs in a data set is calculated. In our example, this would essentially be a count of how many students received a 32, how many received a 36, and so on. To create an ungrouped frequency distribution for the student exam scores, we would need to create a table with two columns—one column containing the various exam scores (sorted from smallest to largest) and another column indicating how frequently each of these scores occurred. Table B.2 shows an example of an ungrouped frequency distribution for the 30 exam scores.

> **ungrouped frequency distribution** a count of the number of times each specific data point or score appears in a data set.

Using this ungrouped frequency distribution, the instructor can readily see that the exam scores ranged from a low of 32 (with one person receiving that score) to a high of 67 (also with one person receiving this score). In addition, she can determine that seven people earned scores of either 50 or 51.

In the current example there are 21 unique exam scores. While this is a manageable number of categories, there are many instances where there are many more unique scores. As a result, the number of categories in an ungrouped frequency distribution becomes unmanageable. In such cases (and even in the present case, as we will see), you might want to create a **grouped frequency distribution** instead.

> **grouped frequency distribution** a count of the number of times specific data points fall into a range of values in a data set.

TABLE B.2

Ungrouped Frequency Distribution for 30 Exam Scores

62	1
67	1
Total	**30**

To create a grouped frequency distribution, the instructor first creates a number of ranges, or classes of scores, to serve as the basis of the distribution. In general, there should be between five and 20 classes, and the classes need to be continuous (i.e., the classes need to encompass all of the scores from lowest to highest). **Table B.3** shows an example of a grouped frequency distribution for the 30 exam scores (each with a width of five scores). To complete the grouped frequency distribution, the instructor needs to determine how many of the 30 exam scores fall into each of the classes. For example, only one person had a score between 30 and 34 (i.e., the person who scored 32), so that class has a frequency of 1. There were two scores in the class of scores 35–39 (a 36 and a 39), so this class has a frequency of 2. The remainder of the frequencies for the classes are determined in a similar fashion.

Using this grouped frequency distribution, the instructor can identify aspects of the data set, such as there were 11 students who scored between 50 and 54, and there were only three students who scored less than 40.

Frequency distributions can be presented either in tabular format (as we have done in **Tables B.2** and **B.3**) or, following the adage that a picture is worth a thousand words, in some type of graphic form such as a histogram or a frequency polygon. **Histograms** are commonly used to graphically represent ungrouped frequency distributions. They are similar to bar charts and are constructed using a set of two axes. One axis, the horizontal or *x*-axis, contains an ordered listing of the various values for the scores from the ungrouped frequency distribution. The other axis, the vertical or *y*-axis, provides the frequency of those scores. **Figure B.1** shows a histogram based on the ungrouped frequency distribution for the 30 exam scores.

> **histogram** a bar chart showing the number of times specific data points fall into a range of values in a data set.

TABLE B.3

Grouped Frequency Distribution for 30 Exam Scores

Exam Score Classes	Frequency	Midpoint
30–34	1	32
35–39	2	37
40–44	5	42
45–49	3	47
50–54	11	52
55–59	5	57
60–64	2	62
65–69	1	67
Total	**30**	

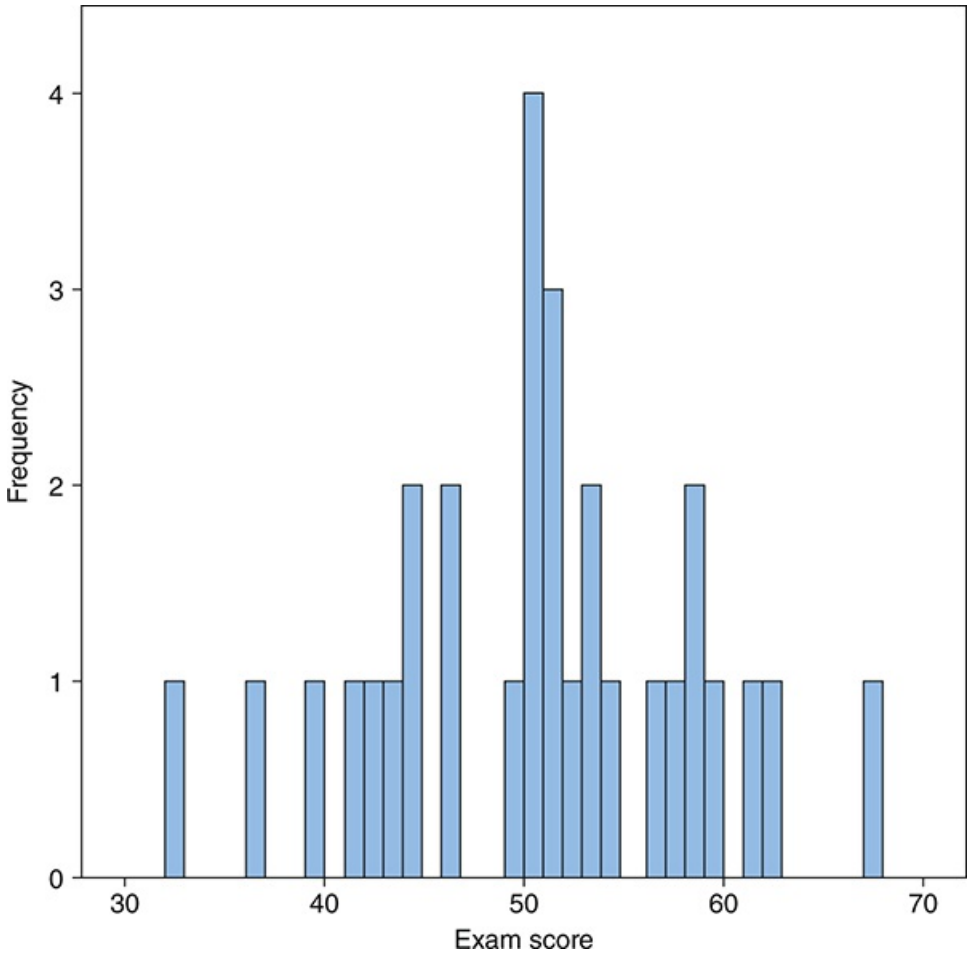

FIGURE B.1 Histogram for 30 exam scores

Frequency polygons are similar to histograms, but they are typically used to graphically represent grouped frequency distributions. Recall that a grouped frequency distribution summarizes the frequency of scores for each of a number of classes or ranges of scores. To create a frequency polygon from a grouped frequency distribution, you need to determine the *midpoint* (i.e., the centre) for each of the classes. In our example, the first class is from 30 – 34, so the midpoint of that class would be $32\left[\frac{30+34}{2}\right]$, with the remaining midpoints for the classes calculated in a similar way (see **Table B.3**). These midpoints are then included on the horizontal axis of the frequency polygon, and the frequencies for each of the classes are included on the vertical axis. **Figure B.2** provides a frequency polygon for the grouped frequency distribution for the 30 exam scores.

frequency polygon a line graph depicting a grouped frequency distribution, which is created by connecting the midpoints of each class of data.

Measures of Central Tendency

Another common use of descriptive statistics is to summarize a collection of data with a

single number that represents the entire data set. Such numbers are called **measures of central tendency**. For example, these numbers may be the most frequent number or a number that is thought to be typical of the data set. The three most common statistical measures of central tendency are the mean, median, and mode.

measures of central tendency numbers used to summarize data sets.

You most likely are already familiar with the **mean**—it is equivalent to the (arithmetic) average of the data set. As you know, to calculate an average (or the mean of a data set), total the numbers in the data set and divide by the total number of numbers. Returning to our example, to calculate the mean, total the 30 numbers and divide by 30. The total of the 30 scores is 1,505, so the mean (or average) of those scores is $\frac{1{,}505}{30} = 50.1667$.

mean the average value in a data set; the sum of all numbers in the set divided by the total number of items in the set.

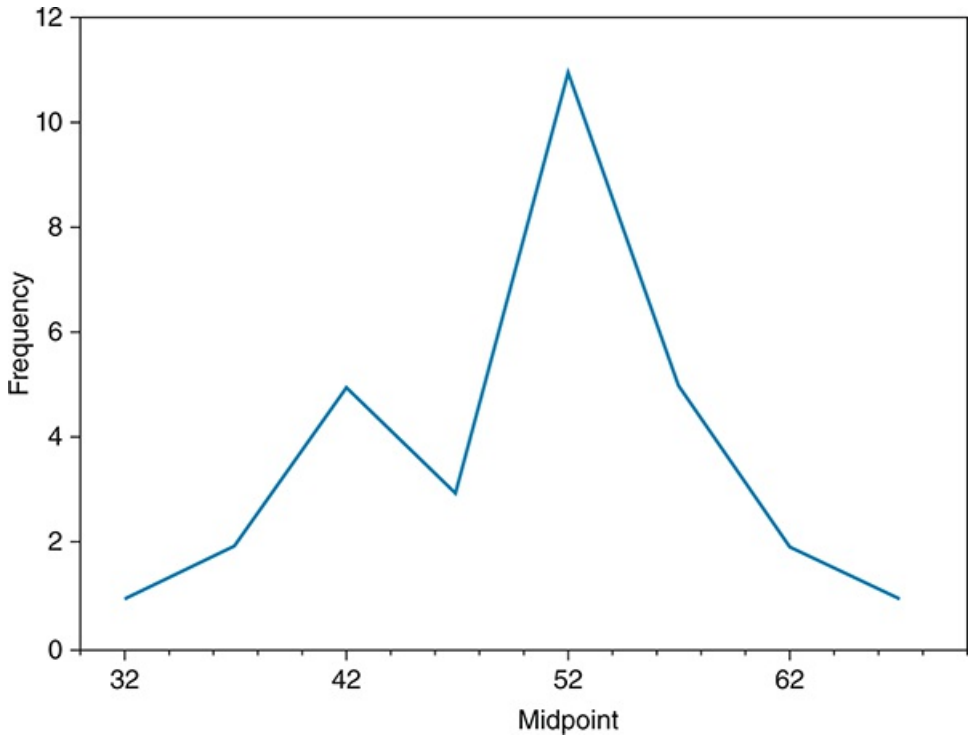

FIGURE B.2 Frequency polygon for 30 exam scores

Statisticians frequently use formulas to summarize the procedures required to calculate various statistical values (like the mean). The formula for the mean is presented below:

$$\alpha = \frac{\sum X}{N}$$

where: μ is the symbol for the mean,[1]

$\sum$ is summation notation and indicates the procedure of totalling the individual values in the data set,

X represents the possible values in the data set, and

N represents the number of observations.

While the mean is the average of the set of data, the **median** represents the midpoint or middle in an ordered set of data. That is, to determine the median for a set of data, first order the set of data (from smallest to largest) and then determine the midpoint of that ordered data set. Our 30 exam scores are sorted in **Table B.1**. Because there is an even number of scores (or observations), the exact midpoint for the data set would be between the 15th and 16th numbers. In cases where the number of observations (or *N*) is even, calculate the median by taking the average of the two middle numbers in the ordered data set. In our example, the 15th highest score is 50 while the 16th highest score is 51, so for this set of data the median is $50.5 \left(\frac{50 + 51}{2} \right)$. In cases where there are an odd number of observations in the data set, the median is simply the middle number in the ordered data set.

median the data set value that represents the midpoint of an ordered set of numbers.

A third measure of central tendency that may be calculated for a set of data is the **mode**, which is the most frequently occurring score or observation. The mode can be easily determined by looking at an ungrouped frequency distribution for the set of data. As **Table B.1** shows, the score of 50 was the most frequent score in our data set of 30 exam scores, with four of the 30 students earning that score. So for this set of data, the mode would be 50. In cases where there are multiple scores that each have equally high frequencies, then the data set has multiple modes (for example, if in our data set four people scored 50 and four people scored 58, then the data set would have two modes, 50 and 58).

mode the most frequent or most common value in a data set.

In summary, for our example set of data we have three measures of central tendency: a mean of 50.1667, a median of 50.5, and a mode of 50. As you can see, for this set of data the three measures of central tendency are similar to one another, and you may wonder which is the "best" measure of central tendency. We will return to this question later in the appendix.

Measures of Variability

Whereas measures of central tendency provide some idea of a typical number in a set of data, they do not tell us anything about how different the numbers in a set of data are from one another. Statistics that do this are known as **measures of variability**.

measures of variability indicators that tell how different the values are within a data set.

The simplest measure of variability for a set of data is the **range**, which is the difference between the largest and the smallest values in a data set. To calculate the range for our 30 exam scores, determine the largest and the smallest score and then take the difference between them. Referring to **Table B.1** the largest score is 67 while the smallest score is 32, so the range of scores is 35 (67 − 32 = 35). One advantage of the range is that it is easy to calculate, but it does have a major shortcoming: for any set of data, the range is based only on two scores and, by definition, these are extreme scores (i.e., they are the largest and smallest scores). As such, the size of the range is influenced by any extreme score, and further, the range only provides limited information about how different each of the numbers in a set of data are from one another.

range the difference between the smallest and the largest value in a data set.

To deal with the shortcomings of the range, there are a couple of related measures of variability: the variance and the standard deviation. Let's say we wanted to calculate, on average, how different each number in a set of data is from the mean. To do this we would have to calculate what is referred to as a *deviation score* for each of the observations (these are calculated by taking the difference between each score and the mean) and then calculate the average of those deviation scores (see **Table B.4**). However, when we follow this procedure a problem arises: to calculate the average of the deviation scores, we have to take the total of those scores and divide this total by the number of scores. Whenever we do this (for any set of scores), the total of the deviation scores will always be 0 (regardless of how different the scores are from one another). Thus, the average of the deviation scores is always 0 for every set of data and, as such, it is not very useful as a possible measure of variability.

Statisticians deal with this problem by calculating another measure of variability, known as the variance. The **variance** is the average of the squared deviation scores. The resulting set of scores has the property that the larger the squared deviation, the further that observation is from the mean. Thus, the larger the variance is for a set of data, the more different the scores are from one another. To calculate the variance for our 30 exam scores, take the average of the squared deviation scores, which gives a variance of 60.94 $\left(60.94 = \frac{1{,}828.167}{30}\right)$; see **Table B.4**).

variance a calculated indicator of the degree to which values in a data set differ from the mean value of that data set; the average of squared deviations about the mean.

The formula for the variance is presented below:

$$\sigma^2 = \frac{\sum (X - \mu)^2}{N}$$

where: σ^2 is the symbol for the variance,[2]

$\sum$ is summation notation and indicates the procedure of totalling the individual

squared deviation scores $(X = \mu)^2$, and

N represents the number of observations.

While the variance is a useful measure of variability in that its magnitude reflects how different the numbers in a set of data are from one another, it also has a major shortcoming: the variance is not in the same metric as the original scores. For example, in calculating the variance, we determined the average of the squared deviations, so for our example the variance was approximately 61. However, that 61 is in the metric of *squared* exam scores, not the original exam scores we started with. To have a measure of variability that is in the same metric as the original scores, we calculate the **standard deviation**—the square root of the variance. In our example of 30 exam scores, the standard deviation is 7.81 $(7.81 = \sqrt{60.94})$. The benefit of using the standard deviation as compared to the variance is that this measure of variability is in the same metric as the original scores.

standard deviation a deviation value that is the square root of the variance; it is a statistical index of how much scores vary within a group.

TABLE B.4

Thirty Exam Scores with the Mean, Deviation Score, and Squared Deviation Score

	Exam Score (X)	Mean (μ)	Deviation Score ($X - \mu$)	Squared Deviation Score $(X - \mu)^2$
	32	50.1667	−18.17	330.029
	36	50.1667	−14.17	200.695

	67	50.1667	16.83	283.360
Totals	**1,505**	**1,505**	**0.00**	**1,828.167**

Frequency Distributions—Again

If we were to obtain a very large number of measurements of one of a variety of human characteristics (e.g., physical characteristics like height or weight or psychological variables like intelligence or anxiety) and plot the frequency of the various values, we would find that the majority of scores fall near the middle of that frequency distribution. Comparatively fewer scores are associated with the more extreme values. Such distributions frequently resemble a theoretical distribution known as a **normal distribution** (sometimes, because of its shape, it may be referred to as a **bell curve**).

> **normal distribution or bell curve** a symmetrical, bell-shaped distribution in which most scores are in the middle with smaller groups of equal size at either end.

Normal distributions all have the same basic shape, but vary depending upon the mean and the standard deviation for the data. For example, scores on the Wechsler Adult Intelligence Scale (WAIS), discussed in Chapter 10, are designed to follow the normal distribution with a mean of 100 and a standard deviation of 15 (see **Figure B.3**).

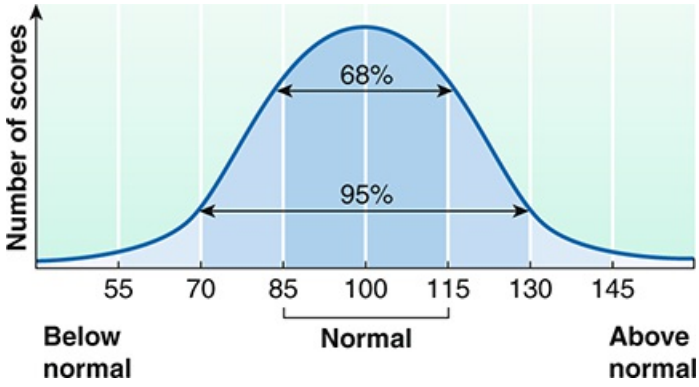

FIGURE B.3 A normal distribution

Once we know that a set of scores (at least theoretically) follows a normal distribution, then we also know certain things about how those scores are distributed. First, the normal distribution is a *symmetrical distribution*—that is, the bottom half of the distribution is the same shape as the top half. Also, with the normal distribution, the three measures of central tendency, the mean, the median, and the mode, all fall in the exact same location. Based on this we know that in the case of WAIS scores that have a mean of 100, 50 percent of individuals will have scores less than 100 and similarly, 50 percent of individuals will have scores greater than 100. Further, theoretically, approximately 68 percent of people will score within plus or minus one standard deviation of the mean (i.e., between 85 and 115), and similarly about 95 percent of people will score within plus or minus two standard deviations of the mean (i.e., between 70 and 130).

Not all variables follow a normal distribution. In many instances, a large data set may have a comparatively small number of scores that are either very low or very high. For example, consider the distribution of 2010–2011 salaries for players from the Toronto Maple Leafs (Sports City, 2011). In this team, as is common in many teams in the NHL, there are a few premiere players who receive considerably higher than normal salaries, which results in a **positively skewed distribution** (sometimes referred to as a *distribution skewed to the right*). As **Figure B.4** reflects, in situations where the distribution is positively skewed, the average (or mean) for the distribution is considerably larger than the median value since the few extremely large salaries are included in the calculation of the mean. The mode also tends to be less than the median, which is also typical in positively skewed distributions.

positively skewed distribution a distribution where most values occur at the lower end of the scale.

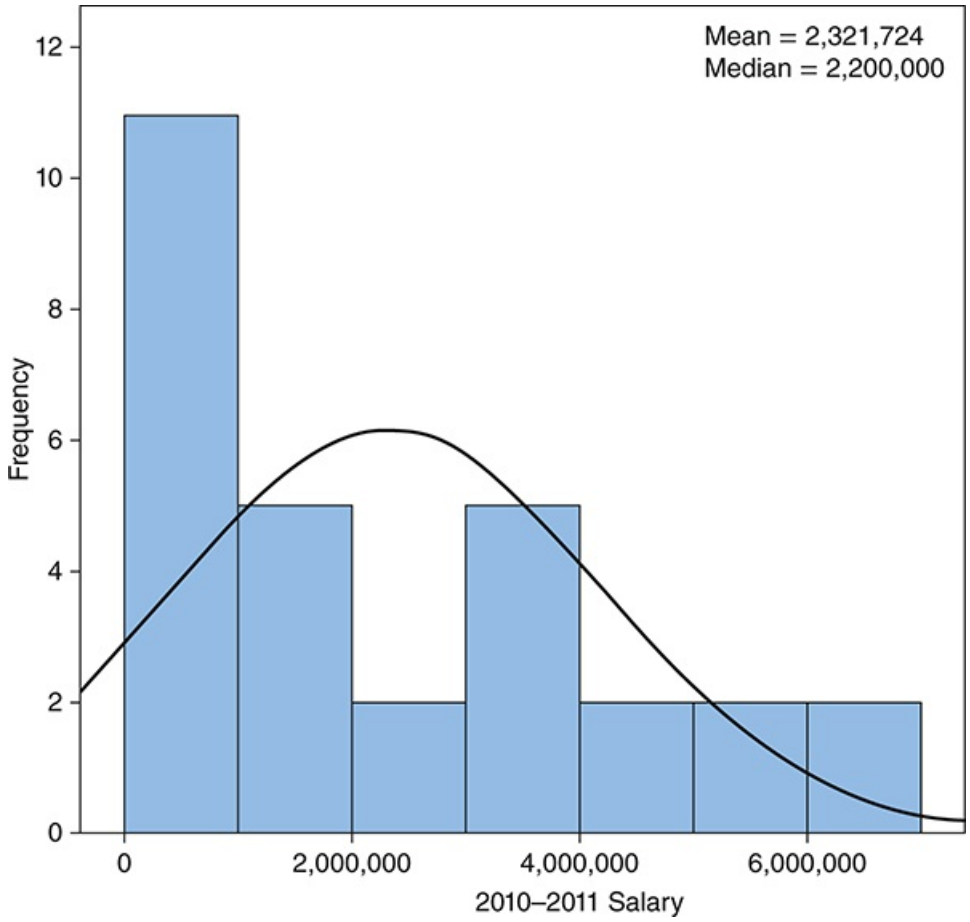

FIGURE B.4 Example of a positively skewed distribution

In other instances, a distribution of scores may contain comparatively few low scores along with many more higher scores. For example, consider a nine-item true–false quiz that an instructor might give to an introductory psychology class with 250 students. Assume that the test is quite easy, so most of the students do very well. This could result in a distribution of scores such as the one depicted in **Figure B.5**. As you can see, the mean is less than the median (again, this is because the value for the mean is influenced by the comparatively few small scores), which is also less than the mode. These types of distributions are called **negatively skewed distributions** (sometimes referred to as a *distribution skewed to the left*).

negatively skewed distribution a distribution where most values occur at the upper end of the scale.

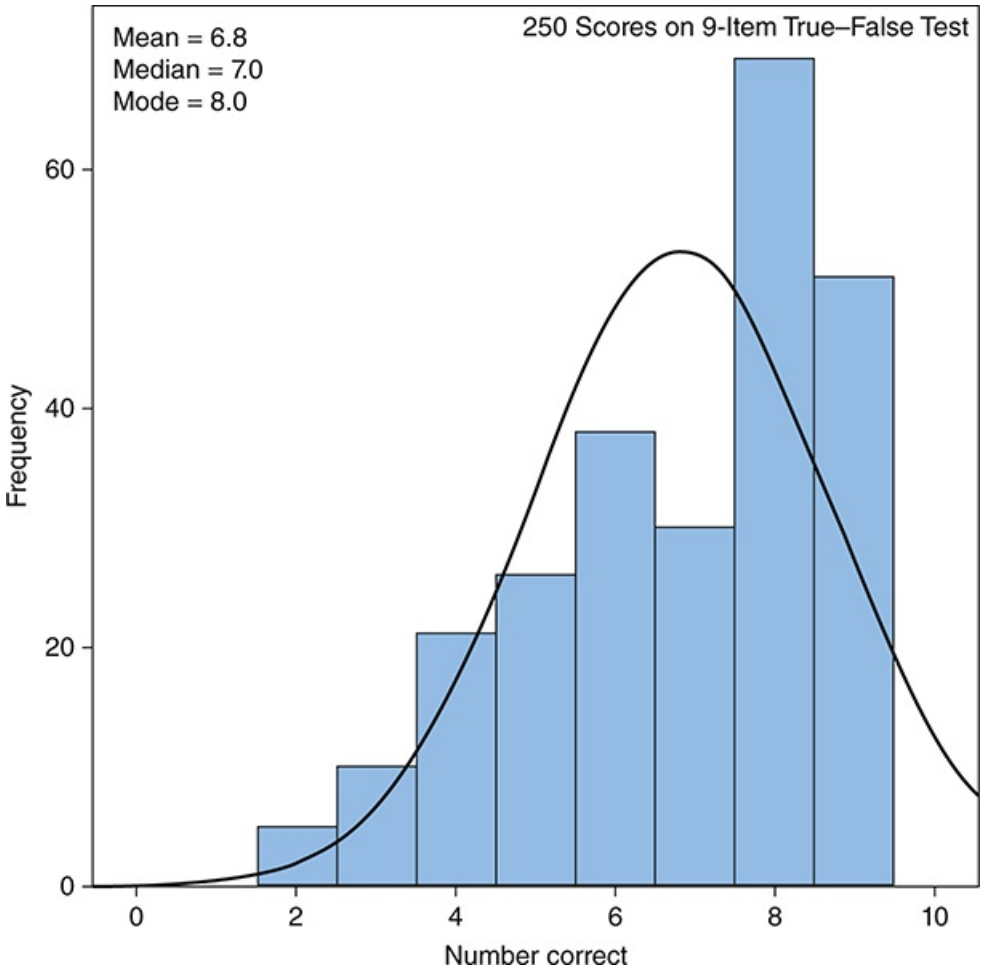

FIGURE B.5 Example of a negatively skewed distribution

In summary, if a distribution has comparatively few small or high scores, the mean may not be the best measure of central tendency since it is the only measure of central tendency that is influenced by these types of extreme scores. In such cases, the median or mode may be a better, more representative measure of central tendency.

Measures of Association

In many situations, psychologists are interested in studying the relationship between two (or more) variables. For example, what is the relationship between exposure to televised violence and actual physical aggression? Or is there a relationship between exposure to actors smoking in the media (e.g., in movies and television) and the likelihood of a teenager deciding to start smoking? In instances such as these, we can quantify and summarize the degree of relationship or association between variables using descriptive statistics known as **measures of association**.

measures of association descriptive statistics that quantify and summarize the degree of relationship or association between variables.

Recall our earlier example where we had scores from 30 students on their first psychology test (refer to this variable as *X*). Suppose that we had also asked those same 30 students the following question: "In the week before the test, how many hours did you spend playing video games?" (call this variable *Y*). **Table B.5** provides a listing of these data.

In instances where we have collected data on two variables from a group of individuals, it is possible to represent the relationship between the two variables using a display known as a **scatterplot** (or scattergram). In this display, values of one of the variables are plotted on the horizontal axis of the graph and the corresponding values of the other variable are plotted on the vertical axis. **Figure B.6** provides a scatterplot of our example data. On average, higher exam scores are associated with students who spent less time playing video games. Similarly, students who received the lower exam scores, on average, spent more time playing video games in the week before the exam.

> **scatterplot** a graph or plot of the values of one variable or measure associated with the values on another variable or measure.

While we can understand the nature of the relationship between two variables using scatterplots, we might want to have an index or number that reflects the nature of that relationship. The most commonly used measure of association between two variables is the **Pearson product-moment correlation coefficient** (often symbolized with an *r* and frequently referred to as simply the correlation coefficient). The correlation coefficient provides an index of the degree of (linear) relationship between two variables, with possible values of the coefficient ranging between −1 and +1. The value of the correlation coefficient reflects both the *magnitude* of the relationship between the two variables and the *direction* of the relationship between the two variables. Positive values of the correlation coefficient ($r > 0.00$) indicate that there is a **positive** or **direct relationship** between the variables. In instances like this, higher values on one of the variables are associated, on average, with higher values on the other variable; similarly, lower values of the one variable are associated, on average, with lower values of the other variable. In cases where the correlation coefficient is negative (i.e., $r < 0.00$), the nature of the relationship between the two variables is referred to as a **negative** or **inverse relationship**. In this case, the lower scores on one variable are, on average, associated with higher scores on the other variable and vice versa (as was the case with our example data).

> **Pearson product-moment correlation coefficient** a statistic indicating the degree of association or relationship between two variables or measures, ranging from −1 to +1.
>
> **positive or direct relationship** a relationship where as the value of one variable increases, so do values in another associated variable.
>
> **negative or inverse relationship** a relationship where as the value of one variable increases, values in another associated variable decrease.

Figure B.7 provides an example of a number of scatterplots depicting varying degrees of relationship between the two variables. The left-most scatterplots reflect instances of positive and negative perfect relationships (i.e., $r = +1$ and $r = -1$). In instances like these, values on one variable change on a one-to-one basis with changes in the other variable and the relationship can be represented with a straight line. Such relationships are rarely observed in real life. As we move to the right in **Figure B.7**, as the degree of relationship between the variables decreases, the data points in the scatterplot no longer fall on a straight line. Further, with decreases in the degree of relationship, the points in the scatterplot fall farther from the straight line.

As previously mentioned, the value of the correlation coefficient reflects both the *direction* and the *magnitude* of the relationship between the two variables. To interpret the magnitude of the relationship reflected, we need to consider the absolute value of the correlation (i.e., ignoring whether or not it is positive or negative). The closer the absolute value of the correlation coefficient is to 1, the stronger the degree of relationship between the two variables. An alternative way of understanding the magnitude of the relationship is to take the square of the correlation coefficient (i.e., r^2). This value is known as the **coefficient of determination** and indicates the degree to which values on one variable can be predicted by knowing the values of the other variable. For example, if the correlation between number of cigarettes smoked and life expectancy were $r = 0.80$, then we could predict with 64 percent accuracy a person's life expectancy based on how much he or she had smoked.

coefficient of determination the degree to which values on one variable can be predicted by knowing the values of the other variable.

To calculate the Pearson product-moment correlation coefficient, take the ratio of the covariance between the two variables (which is another measure of association) and divide that by the product of the standard deviations of the two variables. The covariance between two variables (let's call them X and Y) is defined by the following formula:

$$\sigma_{XY} = \frac{\sum (X - \mu_X)(Y - \mu_Y)}{N}$$

where: σ_{XY} is the symbol for the covariance,[3]

$\sum$ is summation notation and indicates the procedure of totalling the products of each pair of deviation scores $(X - \mu_X)$ and $(Y - \mu_Y)$, and

N represents the number of observations.

Table B.6 shows our example data looking at the relationship between students' exam scores (X) and hours spent playing video games (Y). The table includes the details on the initial calculations required to determine the variances for each of the variables and the covariance between the two variables.

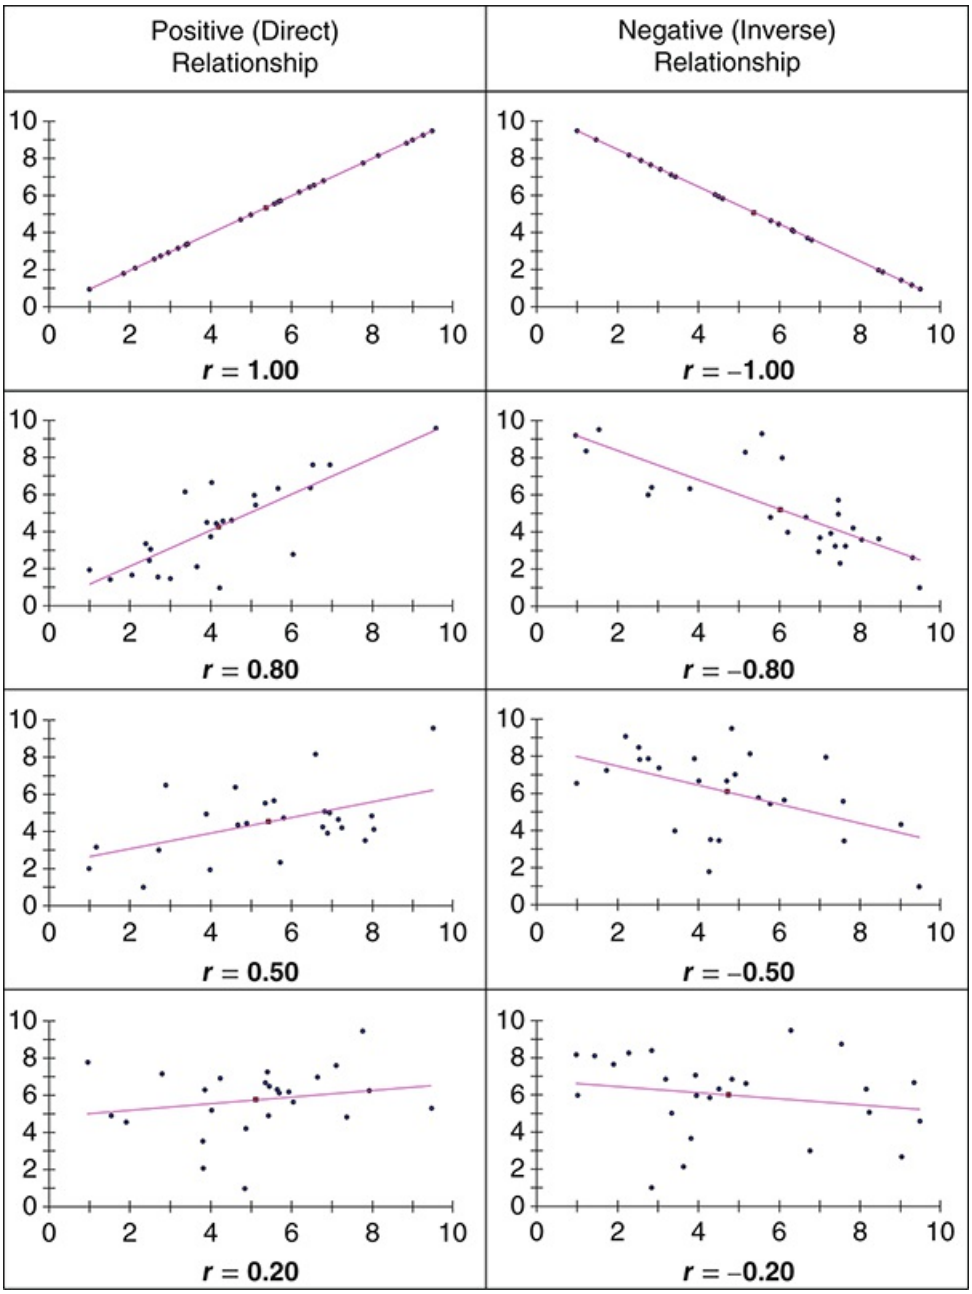

FIGURE B.7 Scatterplots showing various degrees of relationship

First, consider the covariance between the two variables. The numerator for the covariance is based on the sum of the product of the individual pairs of deviation scores (ie., $\sum(X - \mu_X)(Y - \mu_Y)$).

In this example the total is negative, which reflects the inverse relationship that exists between the students' exam scores and the number of hours they spent playing video games. On average, the students who had higher exam scores, and who therefore also had positive deviation scores for that variable ($X - \mu_X$), were more likely to have spent less time playing video games, and therefore had negative deviation scores for that variable ($Y - \mu_Y$).

Further, the reverse is true for students who had lower exam scores. When this happens, the covariance between the two variables will be negative and this will result in the correlation between the two variables being negative as well, since the covariance serves as the numerator for the correlation.[4] For our example data, the covariance between the two variables is:

$$\sigma_{XY} = \frac{\sum (X - \mu_X)(Y - \mu_Y)}{N} = \frac{-1{,}077.83}{30} = -35.93$$

The next step in calculating the correlation coefficient is to determine the standard deviation for each of the variables. Recall that the standard deviation for a variable is the square root of the variance. The variance for each of the two variables can be calculated as shown below:

$$\sigma_X^2 = \frac{\sum (X - \mu_X)^2}{N} = \frac{1{,}828.17}{30} = 60.94 \text{ and } \sigma_Y^2 = \frac{\sum (Y - \mu_Y)^2}{N} = \frac{909.37}{30} = 30.31$$

TABLE B.6

Data Required for Calculating Pearson Correlation Coefficient

Student	Exam Score (X)	Hours Playing Video Games (Y)	$X - \mu X$	$Y - \mu Y$	$(X - \mu X)(Y - \mu Y)$	$(X - \mu X)^2$	$(Y - \mu Y)^2$

16	51	6	0.83	−1.77	−1.47	0.69	3.12
17	51	7	0.83	−0.77	−0.64	0.69	0.59
18	51	4	0.83	−3.77	−3.14	0.69	14.19
19	52	5	1.83	−2.77	−5.07	3.36	7.65
20	53	0	2.83	−7.77	−22.01	8.03	60.32
21	53	4	2.83	−3.77	−10.67	8.03	14.19
22	54	5	3.83	−2.77	−10.61	14.69	7.65
23	56	2	5.83	−5.77	−33.64	34.03	33.25
24	57	5	6.83	−2.77	−18.91	46.69	7.65
25	58	4	7.83	−3.77	−29.51	61.36	14.19
26	58	2	7.83	−5.77	−45.17	61.36	33.25
27	59	0	8.83	−7.77	−68.61	78.03	60.32
28	61	1	10.83	−6.77	−73.31	117.36	45.79
29	62	0	11.83	−7.77	−91.91	140.03	60.32
30	67	3	16.83	−4.77	−80.24	283.36	22.72
Totals (Σ)	**50.167**	**7.767**	**0.00**	**0.00**	**−1,077.83**	**1,828.17**	**909.37**

To obtain the standard deviations for the two variables, take the square roots of the two variances $\left(\text{ie.,} \sigma_X = \sqrt{60.94} = 7.81 \text{ and } \sigma_Y = \sqrt{30.31} = 5.51\right)$. Finally, take the covariance and divide it by the product of the two standard deviations[5]:

$$r = \frac{\rho_{XY}}{\sigma_X \sigma_Y} = \frac{-35.93}{7.81 \times 5.51} = -0.84$$

So, for our 30 students, the correlation between their exam scores and the amount of time spent playing video games is −0.84. In other words, we could predict with about 70 percent accuracy (i.e., 0.84^2) a student's exam score if we knew how many hours that person had spent playing video games. Finally, as discussed in Chapter 2, remember that correlations tell us nothing regarding causality. So even though there is a fairly strong negative relationship between exam scores and video game playing in our example data, we do not know whether one variable causes the other or whether there is some third variable that is responsible for the relationship. So video gaming might reduce exam scores, or low exam scores might increase video gaming, or low exam scores and high amounts of video gaming might both be due to a lack of interest in or commitment to the course in question.

Inferential Statistics

Whereas psychologists (and others) use descriptive statistics to summarize collections of data, they use *inferential statistics* to help them make informed decisions regarding the types of conclusions they can make regarding their research findings. To understand this better, let's begin with some definitions and an example.

Populations and Samples

In most cases, when psychologists conduct research (whether on human participants or animal subjects), what they are doing is collecting observations based on a **sample** of individuals that is drawn from a larger group or **population** (see Figure B.8). Consider a simple experimental study where a psychologist is interested in testing the effectiveness of a new drug to improve memory. It would be impractical (and very expensive) to test every individual who might take the drug, so the researcher obtains a sample of individuals, studies them, and then draws some type of conclusions based on the results of that study. Let's look at this procedure in more detail.

sample a group or set of people or items drawn from a larger population.

population the entire group of individuals about whom we hope to learn (e.g., the Canadian population consists of all Canadians).

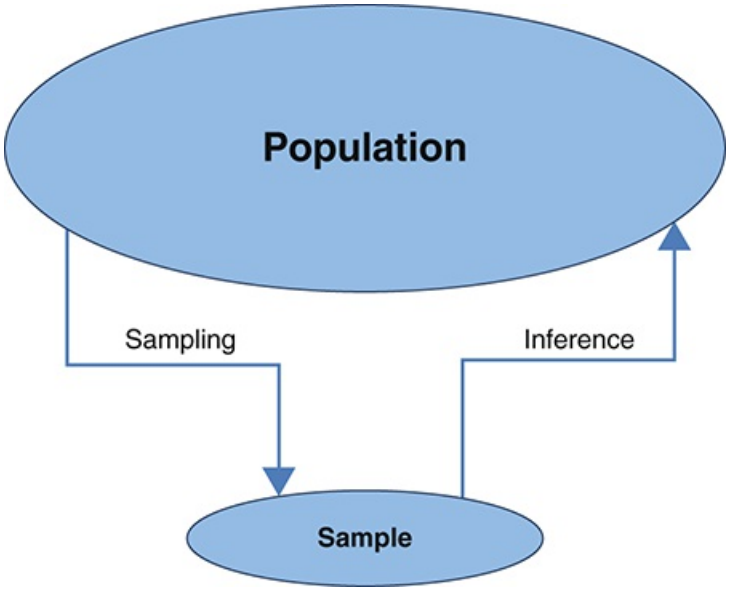

FIGURE B.8 Relationship between population and samples

First, consider the underlying population—the group about which the psychologist ultimately wants to make conclusions—from which the psychologist is going to obtain her sample. In the case of testing a drug that supposedly improves (human) memory, we might consider the population to be all adults in North America. Since the psychologist cannot test the effect of the drug on all members of the population, she instead obtains a sample of individuals from that population. Often the ideal type of sample to obtain would be a **random sample**, in which every member of the population has an equal chance of being selected for the study. However, in many instances it is not possible to obtain a truly random sample. Instead researchers rely on sampling from a group of individuals to which they have access (e.g., first-year psychology students).

random sample a group or set made by randomly selecting people or items from a larger population; like closing your eyes and picking any two socks from your drawer.

Assume that the psychologist has recruited 50 participants for her study. This study will involve two groups: the experimental group, which will receive the drug and then will have their memory tested, and a control group that will consist of participants who are treated exactly the same as the participants in the experimental group with the exception that they will not receive the drug.[6] In conducting the experiment, the researcher might randomly assign 25 participants to each of the two conditions (e.g., participants could be assigned to the experimental vs. control groups based on the results of the flip of a coin). Random assignment helps to ensure that any differences that might have existed between the two groups are evenly distributed between the groups so that the two groups are as similar as possible at the start of the study.

Hypothesis Testing

Assume that memory is assessed in this study with a standard memory test, and the researcher finds that the average score for the experimental group is 50 whereas the average score for the control group is 25. At this point, the psychologist can conclude that, on average, the experimental group had better performance on the memory test than did the control group, which she could attribute to the effect of the drug. However, the more interesting question, and the one that is at the heart of inferential statistics, is whether or not a similar finding would be obtained if the drug were given to other individuals in the population. The answer to this question comes down to the psychologist determining whether or not the difference observed between the two groups in the sample is "big enough" for her to conclude that similar differences would likely occur if the study was conducted again with a different sample of individuals.

To address this question, the psychologist can employ a technique known as **hypothesis testing**. With hypothesis testing, the psychologist sets up two hypotheses: the null hypothesis and the alternative hypothesis. Under the **null hypothesis**, the psychologist asserts that in the underlying population from which the sample was obtained, there is no difference between the average performance of individuals who might receive the drug and those who might not receive the drug (in other words, this null hypothesis asserts that the memory drug is *not* effective). The **alternative hypothesis** would be that in the population from which the sample was obtained, the average performance on the memory test for individuals receiving the memory drug would be better than that for individuals not receiving the drug (in other words, asserting that the memory drug *is* effective).

> **hypothesis testing** testing a statement or claim about a population using a sample and, in its simplest form, looking at experimental and control group differences.
>
> **null hypothesis** an assertion that in the underlying population from which the sample was obtained, there is no difference between the average performance of individuals in one group compared to another.
>
> **alternative hypothesis** an assertion that in the underlying population from which the sample was obtained, there *is* a difference between the average performance of individuals in one group compared to another.

When the psychologist conducts her memory drug study, she obtains her sample of 50

individuals from the underlying population and uses that sample to create two groups. Theoretically, she could have obtained many other, different samples from that population. In this particular study, the researcher finds that there is a 25-point difference between the average memory performance for participants in the control group and those in the experimental group. Now the inferential question is, how likely is it that she would have found a difference of 25 points between the two sample means *if* the null hypothesis was true (i.e., if there really was no difference in people's memory between those who receive the memory drug and those who do not)? To determine the likelihood of this finding, the psychologist needs to consider a theoretical distribution known as a **sampling distribution**. In this case, the psychologist would consider a sampling distribution for the difference between two sample means (or averages) that are taken from an underlying population in which there is no difference between the means. The characteristics of this sampling distribution are based on the variability of the sample data and the size of the samples.

> **sampling distribution** the theoretical distribution of a sample statistic; for example, the difference between two sample means taken from a population.

In our example, assume that the standard deviation for scores on the memory test was 20 for the control group and 30 for the experimental group. If the null hypothesis was true, then we would know theoretically that all possible differences between two sample means would be normally distributed with a mean of 0 and a standard deviation of 7.21.[7] Given that we know the characteristics of the theoretical sampling distribution, we can calculate that the likelihood or probability of finding a difference of 25 points between the two sample means would be very low (in fact, it would be less than 1 chance in 1,000). In this case, the psychologist would reject the null hypothesis and could be reasonably confident in concluding that the finding she obtained in her study was not due to chance and that the drug really had some effect on memory performance.

When psychologists test hypotheses using the procedures outlined above, before analyzing their data, they determine what level of risk they would be willing to take in terms of making an incorrect conclusion. Typically psychologists set the risk of drawing an incorrect conclusion at a level of either *less than 5 in 100* times or, if they want to be more certain (and more conservative) *less than 1 in 100* times. These levels translate to what is known as the **significance level,** or the **rejection level**, for the hypothesis test, and are often reported in the literature as finding a significant difference between the groups at $p < 0.05$ or $p < 0.01$. In practice, if a psychologist ends up rejecting the null hypothesis, she concludes that there is evidence to support the alternative hypothesis (e.g., that the memory drug is effective)—what she cannot say, however, is that she has "proven" the alternative hypothesis. This is because we only have information from the one sample and there is still some possibility (albeit a low one) that the sample she obtained did indeed come from a population where the drug had no effect on memory.

> **significance level** or **rejection level** the level of risk researchers would be willing to take in terms of making an incorrect conclusion.

Effect Size

Whereas inferential statistics provide psychologists with tools to determine the likelihood of the finding in the sample being one that would also occur in the population, they do not provide information regarding the magnitude of the study's effect. For example, while a psychologist may use null hypothesis testing to find that there is a significant difference between memory performance for two groups, the hypothesis test does not tell us about the magnitude or size of the difference—it only allows the psychologist to make a statement regarding the probability of the finding. Researchers can use another category of descriptive statistics, namely **effect size** estimates, in conjunction with hypothesis testing to help them assess the magnitude of research findings. An effect size is a standardized measure that reflects the degree of relationship or size of the difference between two or more variables. Further, since effect sizes are standardized, they can be compared across different studies (Field, 2005).

> **effect size** a standardized measure that reflects the degree of relationship or size of the difference between two or more variables.

Two common categories of effect sizes are (1) group difference indices that estimate the magnitude of the difference between two (or more) groups; and (2) strength of association indices that estimate the degree of shared variation between two (or more) variables (Ferguson, 2016). In simple studies that involve examining the difference in average performance between two groups, Cohen's *d* is the most common effect size. Cohen's *d* is the standardized difference between two population means and can be estimated by taking the difference between the two sample means and dividing this by the standard deviation for the data. In the previous memory study example there was a 25-point difference between the two sample means; if we divide that by the standard deviation[8] of the data, then Cohen's *d* equals $0.98 \left(d = \frac{25}{25.5} = 0.98 \right)$. In terms of interpreting effect sizes (specifically Cohen's *d*), a frequently used rule-of-thumb is to define effect sizes as "small, *d* = .2," "medium, *d* = .5," and "large, *d* = .8" (Cohen, 2003). Thus, for the example data, we could conclude that the memory drug has a large effect.

For non-experimental studies, a common effect size that is a measure of association is the Pearson correlation coefficient (i.e., *r*). In terms of interpreting *r* as an effect size, Cohen (1992) suggests the following: "small, *r* = .1," "medium, *r* = .3," and "large, *r* = .5" Recall that squaring the correlation coefficient provides the coefficient of determination, which tells us how much of the variability in one variable can be predicted based on scores from the other variable. With this in mind, for non-experimental research, if one could account for 1 percent of the variability, then you would have a small effect; if you could account for 9 percent of the variability, then you would have a medium effect; and if you could account for 25 percent of the variability, you would have a large effect.

Why Statistics Matter

This appendix has hopefully provided you with some insight into several of the basic

statistical procedures used by psychologists as tools to summarize and interpret the data they collect as part of their research studies. Students of psychology are often surprised by the degree to which the study of psychology requires at least a basic familiarity with statistics. However, only with this type of understanding will students become better consumers of psychological research and thereby become better able to critically evaluate the claims made by psychologists. In fact, students who choose to major in psychology as undergraduates will most likely require further instruction in statistics. A survey of requirements for undergraduate degrees in psychology by the American Psychological Association showed that the vast majority of universities and colleges require at least one course in statistics (Norcross et al., 2016). So if you are interested in pursuing a degree in psychology, you can expect to encounter even more statistics.

Notes

1 μ is the symbol for the mean of a population, whereas $\overline{X}$ is the symbol for the mean of a sample. The distinction between populations and samples is discussed later in this appendix.

2 σ^2 is the symbol for the variance of a population, whereas s^2 is the symbol for the variance of a sample. The distinction between populations and samples is discussed later in this appendix.

3 σ_{XY} is the symbol for the covariance of a population, whereas S_{XY} is the symbol for the covariance of a sample. The distinction between populations and samples is discussed later in this appendix.

4 Note that when there is a positive relationship between the two variables, higher scores on one variable will on average be associated with higher scores on the other variables (thus the product of the corresponding deviation scores will be positive). Additionally,

lower scores on one variable will on average be associated with lower scores on the other variable (and in this case, the two corresponding deviation scores will both be negative and therefore their product will be positive). In cases like this, the covariance between the two variables will be a large positive value, which will result in the correlation between the two variables being positive.

5 This formula for the correlation coefficient is really more of a "definitional" formula and would only be used if the number of observations was small. In most instances, the correlation coefficient is calculated using one of several alternative "calculational" formulas.

6 In a well-designed study, the participants in the control group would not know that they were in the control group and would be administered some type of placebo (e.g., a sugar pill).

7 This standard deviation is known as the *standard error of the differences between means* and equals $\sqrt{\frac{20^2}{25} + \frac{30^2}{25}} = 7.21$.

8 In the case of the example study, the standard deviation of the data is obtained by using the pooled standard deviation, which can be calculated as

$$s^\star = \sqrt{\frac{(n_1 - 1)\, s_1^2 + (n_2 - 1)\, s_2^2}{n_1 + n_2 - 2}} = \sqrt{\frac{(25 - 1)20_1^2 + (25 - 1)30_2^2}{25 + 25 - 2}}$$

$$= 25.5$$

Glossary

A

ABC model of attitudes
a model proposing that attitudes have three components: the affective component, the behavioural component, and the cognitive component.

abnormal psychology the scientific study of psychological disorders. **absolute pitch**
the ability to recognize or produce any note on a musical scale. **absolute refractory period**
a very brief period of time after an action potential, during which a neuron is completely unable to fire again.

absolute threshold
the minimal stimulus necessary for detection by an individual 50 percent of the time.

academic psychology
a branch of psychology focusing on research and instruction in the various areas or fields of study in psychology.

accommodation
one of two ways of acquiring knowledge, defined by Piaget as the alteration of pre-existing mental frameworks to take in new information.

action potential
a sudden positive change in the electrical charge of a neuron's axon, also known as a spike or firing; action potentials are rapidly transmitted down the axon.

activation-synthesis model
theory that dreams result from the brain's attempts to synthesize or organize random internally-generated signals and give them meaning.

actor–observer effect
the discrepancy between how we explain other people's behaviour (dispositionally) and how we explain our own behaviour (situationally).

acute stress disorder
an anxiety disorder in which fear and related symptoms are experienced soon after a traumatic event and last less than a month.

acute stressor
a stressful situation or circumstance that happens in the short term and has a definite endpoint.

adaptive theory of sleep
theory that organisms sleep for the purpose of self-preservation, to keep away from predators that are more active at night.

addiction
psychological or physical compulsion to take a drug, resulting from regular ingestion and leading to maladaptive patterns of behaviour and changes in physical response.

afferent neurons neurons that carry sensory information from the body to the CNS.

affiliation
the need to form attachments to other people for support, guidance, and protection.

ageusia inability to taste. **aggression**
a broad range of behaviours intended to harm others. **agoraphobia**
a phobia that makes people avoid public places or situations in which escape might be difficult or help unavailable should panic symptoms develop.

agrammatism
a neurological condition arising from damage to a brain region just anterior to Broca's area, where the patient is incapable of using words in grammatical sequence.

alcoholism long-term pattern of alcohol addiction. **algorithm**
a problem-solving strategy that always leads to a solution. **allele** variation of a gene.

altered states of consciousness
a change in a person's ability to be fully aware of their external surroundings and internal states.

altruism self-sacrificing behaviour carried out for the benefit of others. **Alzheimer's disease**
most common form of dementia, usually beginning with mild memory problems, lapses of attention, and problems in language, and progressing to difficulty with even simple tasks and recall of long-held memories.

amnestic disorders organic disorders in which memory loss is the primary symptom.

amotivation the state of being without motivation. **amygdala**
brain area involved in processing information about emotions, particularly fear.

analogous
characteristics that are similar between species and that *cannot* be traced back to a common ancestor.

anorexia nervosa
eating disorder in which individuals under-eat and have a distorted body image of being overweight.

anosmia inability to detect odours. **anterograde amnesia**
ongoing inability to form new memories after an amnesia-inducing event. **antianxiety drugs** psychotropic drugs that reduce tension and anxiety. **antidepressant drugs**
psychotropic drugs that lift the mood of depressed people. **antipsychotic drugs**
medications that help remove the symptoms of schizophrenia. **antipsychotic drugs**
psychotropic drugs that help correct grossly confused or distorted thinking. **antisocial personality disorder**
a personality disorder characterized by extreme and callous disregard for the feelings and rights of others.

applied psychology

the branch of psychology applying psychological principles to practical problems in other fields, such as education, marketing, or industry.

approach–approach conflict
conflict that occurs when a person must choose between two equally desirable options.

approach–avoidance conflict
conflict that occurs when any available choice has both desirable and undesirable qualities.

approach motivation
the desire to experience a positive outcome following a behaviour. **assimilation**

one of two ways of acquiring knowledge, defined by Piaget as the inclusion of new information or experiences into pre-existing schemes.

association cortex
areas of the cortex responsible for complex functions, including higher-order sensory processing, thinking, and planning—all of cortex that is neither purely sensory nor motor.

associative learning learning that involves forming associations between stimuli.

attachment
a significant emotional connection to another person, such as a baby to a primary caregiver.

attitudes relatively stable and enduring evaluations of things and people. **attributions**

causal explanations of behaviour. **automatic processing**

encoding of information with little conscious awareness or effort. **automatic thoughts**

specific upsetting thoughts that arise unbidden. **autonomic nervous system**

portion of the peripheral nervous system that comprises the sympathetic and parasympathetic nervous systems.

availability heuristic judging easily-recalled events as more common. **aversion therapy**
therapy designed to help clients to acquire anxiety responses to stimuli that the clients have been finding too attractive.

avoidance–avoidance conflict
conflict that occurs when a person must choose between two equally undesirable options.

avoidance motivation
the desire to avoid the experience of a negative outcome following a behaviour. **axon terminal** the end of a neuron's axon, from which neurotransmitters are released. **axon**

the part of the neuron that carries information away from the cell body toward other neurons.

B

babbling babies' production of meaningless sounds. **basic emotions**

a group of emotions preprogrammed into all humans regardless of culture. **basilar**

membrane structure in the cochlea where the hair cells are located. **behavioural genetics** a subfield of psychology looking at the influence of genes on human behaviour.

behaviourism
a branch of psychological thought arguing that psychology should study only directly observable behaviours rather than abstract mental processes.

behaviourism the systematic study and manipulation of observable behaviour.

behaviour modification
a systematic approach to change behaviour using principles of operant conditioning.

behaviour
observable activities of an organism, often in response to environmental cues. **biases**
distorted beliefs based on a person's subjective sense of reality. **binge eating disorder**
out-of-control eating of an unusually large amount of food in a single event, often multiple times per week, over several months or years.

bioecological model of intelligence
Ceci's theory that intelligence is a function of the interactions among innate potential abilities, environmental context, and internal motivation.

biological therapy
the use of physical and chemical procedures to help people overcome psychological difficulties.

bipolar disorder
a mood disorder in which periods of mania alternate with periods of depression. **body mass index (BMI)** weight-to-height ratio. **body weight set point**
a weight that individuals typically return to even after dieting or overeating.

borderline personality disorder
a personality disorder characterized by severe instability in emotions and self-concept and high levels of volatility.

bottom-up processing
perception that proceeds by transducing environmental stimuli into neural impulses that move into successively more complex brain regions.

bounded rationality
the fact that in many situations, our ability to make clear rational decisions is limited or "bounded" by things like a lack of information, time constraints, or emotions attached to aspects of the problem we are trying to solve.

brain entropy
the number of neural states, or neural configurations, a brain can access during a task.

Broca's aphasia
a neurological condition arising from damage to Broca's area where the patient is unable to produce coherent speech.

Broca's area a brain region located in the frontal lobe important for speech production.

bulimia nervosa
eating disorder in which individuals binge and then engage in purging-type behaviour.

C

Cannon-Bard theory of emotion
a theory proposing that the subjective experience of emotion and the activation of the sympathetic nervous system (that is, bodily arousal) occur simultaneously.

case study study focusing on a single person. **catatonia**
extreme psychomotor symptoms of schizophrenia, including catatonic stupor, catatonic rigidity, and catatonic posturing.

catharsis
reliving of past repressed feelings as a means of settling internal conflicts and overcoming problems.

cellular clock theory
theory suggesting that we age because our cells have built-in limits on their ability to reproduce.

cephalocaudal pattern
a pattern in which growth and development proceed from top to bottom. **cerebellum**
the part of the brain, near the base of the back of the head, important for motor coordination.

cerebral cortex
the largest portion of the brain, responsible for complex behaviours including language and thought.

child-directed speech
speech characterized by exaggerated emotional responses and a slower pace that is cross-culturally common among caregivers communicating with babies and young children.

chromosomes
strands of DNA; each human being has chromosomes, distributed in pairs. **chronic stressor**
a stressful situation or circumstance that is more long term and often lacks a definite endpoint.

chunking
grouping bits of information together to enhance ability to hold that information in working memory.

circadian rhythm
pattern of sleep–wake cycles that in human beings roughly corresponds to periods of daylight and night.

classical conditioning
a form of associative learning between two previously unrelated stimuli that results in a learned response.

client-centred therapy
an approach to therapy founded by Carl Rogers, based on the notion that the client is an equal and that positive gains are made by mirroring clients' thoughts and feelings in an atmosphere of unconditional positive regard.

client-centred therapy
humanistic therapy designed to help clients experience unconditional positive regard and look at themselves honestly and acceptingly.

clinical and counselling psychology
the study of abnormal psychological behaviour and interventions designed to change that behaviour.

cochlea fluid-filled structure in the inner ear; contains the hair cells. **codominance**
what occurs when in a heterozygous combination of alleles, both traits are expressed in the offspring.

cognition mental processes of thinking and knowing. **cognitive control**
the ability to direct thought in accord with one's intentions. **cognitive development**
changes in thinking that occur over the course of time. **cognitive dissonance**
a state of emotional discomfort people experience when they hold two contradictory beliefs or hold a belief that contradicts their behaviour.

cognitive-mediational theory of emotion
a theory proposing that cognitive interpretations, particularly appraisals, of events are the keys to experiences of emotion.

cognitive neuroscience
the study of mental processes and how they relate to the biological functions of the brain.

cognitive psychology
the field of psychology studying mental processes as forms of information processing, or the ways in which information is stored and operated in our minds.

cognitive therapy
Beck's cognitive therapy technique designed to help clients recognize and change their dysfunctional thoughts and ways of thinking.

cognitive triad
a pattern of thinking in which individuals repeatedly interpret their experiences, themselves, and their futures in negative ways that lead them to feel depressed.

cohort-sequential design
blended cross-sectional and longitudinal research, designed to look at how individuals from different age groups compare to one another and to follow them over time.

collectivist
a culture whose members focus more on the needs of the group and less on individual desires.

common ancestor
an organism that is common to the evolutionary history of two or more living species.

community mental health treatment
treatment programs that emphasize community care, including an emphasis on prevention.

comorbidity

the condition in which a person's symptoms qualify him or her for two or more diagnoses.

compulsions
irrational repetitive and rigid behaviours or mental acts that people feel compelled to perform to prevent or reduce anxiety.

concentration gradient
the difference in concentration of sodium ions inside and outside of the neuron.

concrete operational stage
Piagetian stage during which children are able to talk about complex relationships, such as categorization and cause and effect, but are still limited to understanding ideas in terms of real-world relationships.

conditioned response (CR)
a physical response elicited by a conditioned stimulus; it is acquired through experience and is usually the same as the unconditioned response.

conditioned stimulus (CS)
a neutral stimulus that eventually elicits the same response as an unconditioned stimulus with which it has been paired.

conditioned taste aversion
a form of classical conditioning whereby a previously neutral stimulus (often an odour or taste) elicits an aversive reaction after it's paired with illness (nausea).

conditioning the association of events in the environment. **cones**

photoreceptors responsive to colours. **confirmation bias**

tendency to look for information that meets our expectations. **conflict**

discomfort brought about by two or more goals or impulses perceived to be incompatible.

conformity the tendency to yield to social pressure. **conscious motivations**

motivations that people are aware of and can verbalize. **consciousness**

our immediate awareness of our internal and external states. **consciousness**

personal awareness of ongoing mental processes, behaviours, and environmental events.

conservation
the understanding that certain properties of an object (such as volume and number) remain the same despite changes in the object's outward appearance.

contents of consciousness
specific thoughts we are aware of about our internal states or external surroundings.

content validity
the degree to which the content of a test accurately represents what the test is intended to measure.

context
the original location where you first learned a concept or idea, rich with retrieval cues that will make it more likely you will be able to recall that information later if you are in that same location or context.

continuous reinforcement
what occurs when behaviour is reinforced every time it occurs. **control group**
group that has not been or will not be exposed to the independent variable.

convergence inward movement of the eyes to view objects close to oneself.

convergent evolution
the development of similar physical characteristics or behaviours in different species that do not share a common ancestor; occurs because of exposure to similar environmental conditions for different species.

coping efforts to manage, reduce, or tolerate stress. **corpus callosum**
bundle of axons that allows communication from one side of the cortex to the other.

correlation coefficient
statistic expressing the strength and nature of a relationship between two variables.

correlation predictable relationship between two or more variables. **couple therapy or relationship counselling**
therapy format in which a therapist works with two people who are in a long-term relationship.

creativity the ability to produce ideas that are both original and valuable. **critical period**
a window of time in development during which certain influences are *necessary* for appropriate formation of the brain.

critical periods
points in development when an organism is extremely sensitive to environmental input, making it easier for the organism to acquire certain brain functions and behaviours.

cross-cultural psychology
the study of what is generally or universally true about human beings regardless of culture.

cross-sectional design
a research approach that compares groups of different-aged people to one another.

cultural psychology
the study of how cultural practices shape psychological and behavioural tendencies and influence human behaviour.

cultural universality behaviours and practices that occur across all cultures. **culture**
a set of shared beliefs and practices that are transmitted across generations. **culture-sensitive therapies**
approaches that seek to address the unique issues faced by members of cultural minority groups.

D

daily hassles
everyday annoyances that contribute to higher stress levels; also known as *micro-stressors*.

deafness loss or lack of hearing. **debriefing**

the supplying of full information to participants at the end of their participation in a research study.

decay theory

theory of forgetting, suggesting that memories fade over time due to neglect or failure to access over long periods of time.

decision making evaluating and choosing from among options. **deductive reasoning**

reasoning proceeding from broad basic principles applied to specific situations. **deep brain stimulation**

a procedure in which implanted electrodes deliver constant low stimulation to a small area of the brain; used to treat severe depression, Parkinson's disease, and epilepsy.

defence mechanisms

unconscious tactics employed by the ego to protect the individual from anxiety.

delusions blatantly false beliefs that are firmly held despite evidence to the contrary.

dementia

severe memory problems combined with losses in at least one other cognitive function, such as abstract thinking or language.

dendrites the parts of neurons that receive input from other neurons. **denial**

a defence mechanism; the process of refusing to recognize an existing situation.

deoxyribonucleic acid (DNA) molecules in which genetic information is enclosed.

dependent variable

condition or event that you expect to change as a result of variations in the independent variable.

depolarization

what occurs when the inside of the neuron membrane becomes *less* negative relative to the outside.

depressants class of drugs that slow the activity of the central nervous system.

depression

a persistent sad state in which life seems dark and its challenges overwhelming.

descriptive research methods

studies that allow researchers to demonstrate a relationship between the variables of interest, without specifying a causal relationship.

developmental psychology

the study of changes in behaviour and mental processes over time and the factors that influence the course of those constancies and changes.

developmental psychopathology

the study of how problem behaviours evolve as a function of a person's genes and early experiences, and how these early issues affect the person at later life stages.

diagnosis

a clinician's determination that a person's cluster of symptoms represents a particular disorder.

Diagnostic and Statistical Manual of Mental Disorders (DSM)
the leading classification system for psychological disorders in Canada; DSM-5 is the current version.

difference threshold or just noticeable difference
the minimal difference between two stimuli necessary for detection of a difference between the two.

discrete trait a trait that results as the product of a single gene pairing. **dishabituation**
a form of non-associative learning whereby there is a recovery of attention to a novel stimulus following habituation.

disorder of written expression
a disorder experienced as impairment in the ability to create the written word.

dissociation a splitting of consciousness into two dimensions. **dissociative disorder**
a psychological disorder characterized by major loss of memory without a clear physical cause; types include *dissociative amnesia*, *dissociative fugue*, and *dissociative identity disorder*.

distress stress caused by unpleasant situations or circumstances. **dominant trait**
a trait that is expressed in a phenotype, no matter whether the genotype is homozygous or heterozygous for the trait.

dopamine
neurotransmitter produced by neurons in the hind brain and involved in movement and reward mechanisms.

double-blind procedure
study in which neither the participant nor the researcher knows what treatment or procedure the participant is receiving.

Down syndrome
an inherited disorder, usually caused by the presence of extra chromosomal material on the twenty-first chromosome, that results in intellectual disability.

dysexecutive syndrome
impairments in the ability to control and direct mental activities.

E

efferent neurons
neurons that carry information out from the CNS to the muscles and glands. **effortful processing** encoding of information through careful attention and conscious effort. **ego**
according to psychoanalytic theory, the personality element that works to help satisfy the drives of the id while complying with the constraints placed on behaviour by the environment.

egocentrism
flaws in children's reasoning based on their inability to take another person's perspective.

electroconvulsive therapy (ECT)

use of electric shock to trigger a brain seizure in hopes of relieving abnormal functioning.

electrostatic pressure
the force that drives ions that are of a similar charge away from one another or attracts two ions of opposite charges toward each other.

emotional intelligence
an individual's ability to perceive, express, assimilate, and regulate emotion. **emotion**

an intrapersonal state that occurs in response to either an external or an internal event and typically involves a physiological component, a cognitive component, and a behavioural component.

emotion-focused coping
coping strategies focused on changing one's feelings about the stressor. **empirical**

able to be tested in objective ways. **empirically supported or evidence-based treatment movement**
movement to help clinicians become more familiar with and apply research findings concerning the effectiveness of particular treatments.

encoding
a basic activity of memory, involving the recording of information in our brain.

encoding specificity principle
a theoretical framework that asserts that memory retrieval is more efficient when the information available at retrieval is similar to the information available at the time of encoding.

endocrine system the system that controls levels of hormones throughout the body.

endorphins and enkephalins
chemicals that belong to a naturally occurring class of opiates that reduce pain in the nervous system.

epigenetic
changes in gene expression that are independent of the DNA sequence of the gene.

episodic memory a person's memory of personal events or episodes from his life.

equifinality
the idea that different children can start from different points and wind up at the same outcome.

equilibrium balance in a mental framework. **eustress**

the optimal level of stress needed to promote physical and psychological health.

evolution a process of change over time. **evolutionary psychology**

a field of study believing that the body and brain are products of evolution and that genetic inheritance plays an important role in shaping the complete range of thoughts and behaviours.

evolutionary psychology
field of study that examines how the process of evolution has shaped the body and brain via the interaction of our genes and the environment to produce our thoughts and behaviours.

evolution by natural selection
the differential likelihood between members of a species in their ability to survive and reproduce.

executive function
the brain's ability to control and manage the mental processing of information.

experimental group group that is exposed to the independent variable. **experiment**
controlled observation in which researchers manipulate the presence or amount of the independent variable to see what effect it has on the dependent variable.

explicit memory
memory that a person can consciously bring to mind, such as your middle name.

extinction
reduction of a conditioned response after repeated presentations of the conditioned stimulus alone.

extrinsic motivation
engaging in a behaviour due to the influence of factors outside ourselves.

F

facial efference sensory feedback from facial muscular activity. **facial-feedback theory of emotion**
a theory proposing that subjective experiences of emotion are influenced by sensory feedback from facial muscular activity, or facial efference.

factor analysis
a statistical method for determining whether certain items on a test correlate highly, thus forming a unified set, or cluster, of items.

family systems theory
a theory holding that each family has its own implicit rules, relationship structure, and communication patterns that shape the behaviour of the individual members.

family therapy
a format in which therapists meet with all members of a family to help the whole family to change.

fitness
the ability of an individual to successfully grow to maturity and have offspring that perpetuate the existence of the species that the individual belongs to.

five-factor model
an empirically derived trait model that proposes five major trait categories: agreeableness/disagreeableness, extroversion/introversion, neuroticism/stability, conscientiousness/irresponsibility, and openness to experience/unimaginativeness.

fixed interval schedule
a schedule of reinforcement that occurs every time a specific time period has elapsed.

fixed mindset
a belief that talent is innate and that skill in a particular area is not determined by hard work and effort.

fixed ratio schedule
a schedule of reinforcement that occurs after a specific number of responses.

flashbacks
recurrence of the sensory and emotional changes after the LSD has left the body.

flashbulb memories
detailed and near-permanent memories of an emotionally significant event, or of the circumstances surrounding the moment we learned about the event.

Flynn effect an observed rise in average IQ scores throughout the world over time.

forgetting the inability to recall information that was previously encoded into memory.

formal operational stage
Piaget's final stage of cognitive development when children achieve hypothetical deductive reasoning and the ability to think abstractly.

fossilize the geological process of turning biological material into stone. **fovea**
centre of the retina, containing only cones, where vision is most clear. **free association**
psychodynamic therapy technique of allowing clients to freely talk about whatever they want.

free nerve endings
sensory receptors that convert physical stimuli into touch, pressure, or pain impulses.

free-radical theory
theory suggesting we age because special negatively-charged oxygen molecules become more prevalent in our body as we get older, destabilizing cellular structures and causing the effects of aging.

frontal lobe
lobe of the cortex involved in many functions, including movement and speech production.

frustration an emotion people experience when thwarted in pursuit of a goal.

functional fixedness tendency to view objects as having only one function.

functionalism
a philosophical approach that considers how mental processes function to adapt to changing environments.

fundamental attribution error
the tendency to use dispositional attributions to explain the behaviour of other people.

G

gate control theory of pain
theory that certain patterns of neural activity can close a "gate" to keep pain information from travelling to parts of the brain where it is perceived.

gender-sensitive or feminist therapies
approaches that seek to address the unique pressures of being female. **general adaptation syndrome (GAS)**

a three-stage response to stress identified by Hans Selye; the stages are alarm, resistance, and exhaustion.

generalized anxiety disorder (GAD)
an anxiety disorder in which people feel excessive anxiety and worry under most circumstances.

genes basic building blocks of our biological inheritance. **genotype**

a person's genetic inheritance. **Gestalt psychology**

the field of psychology arguing that we have inborn tendencies to structure what we see in particular ways and to structure our perceptions into broad perceptual units.

***g* factor**
a theoretical general factor of intelligence underlying all distinct clusters of mental ability; part of Spearman's two-factor theory of intelligence.

glia the cells that, in addition to neurons, make up the nervous system. **grit**

long-term perseverance toward a goal. **group**

an organized, stable collection of individuals in which the members are aware of and influence one another and share a common identity.

group polarization
the intensification of an initial tendency of individual group members brought about by group discussion.

group therapy
psychotherapy format in which a therapist sees several clients at the same time.

groupthink
a form of faulty group decision making that occurs when group members strive for unanimity, and this goal overrides their motivation to realistically appraise alternative courses of action.

growth mindset
a belief that hard work and effort can improve a person's skill or talent in a particular area.

gustatory sense our sense of taste.

H

habituation
a form of non-associative learning whereby repeated presentation of a stimulus leads to a reduction in response.

habituation
the process of habituating, in which individuals pay less attention to a stimulus after it is presented to them over and over again.

hair cells sensory receptors that convert sound waves into neural impulses.

hallucinations
imagined sights, sounds, or other sensory events experienced as if they were real.

hallucinogens

substances that dramatically change one's state of awareness, causing powerful changes in sensory perception.

Hawthorne effect
what happens when people who are being observed in studies or at their workplace improve or change some of their behaviour simply because they are being watched or studied, not in response to an experimental manipulation.

hedonic principle
the principle that we avoid painful experiences and approach pleasurable experiences.

hemispheres two sides of the brain. **heritability coefficient**
a correlation coefficient used to indicate the contribution of heredity to some characteristic, such as intelligence.

heritability
the amount of a given trait that can be attributed to inherited genetic factors.

heterozygous having parents contribute two different alleles to offspring. **heuristic**
a shortcut thinking strategy. **higher order conditioning**
what occurs when a previously conditioned stimulus functions as if it were an unconditioned stimulus for further conditioning.

hindbrain
the part of the brain closest to the spinal cord that consists of the medulla, the pons, and the cerebellum; the reticular formation begins here and extends to the midbrain.

hippocampus brain region important for certain types of learning and memory.

homeostasis
a tendency of the body to maintain itself in a state of balance or equilibrium.

homologous
characteristics that are similar between species and that can be traced back to a common ancestor.

homozygous
having both parents contribute the same genetic material for a particular trait.

humanistic psychology
theory of psychology that sought to give greater prominence to special and unique features of human functioning.

hyperpolarization
what occurs when the inside of the neuron membrane becomes *more* negative relative to the outside.

hypnagogic state a pre-sleep period often characterized by vivid sensory phenomena.

hypnosis
a seemingly altered state of consciousness during which individuals can be directed to act or experience the world in unusual ways.

hyposmia reduced ability to detect odours. **hypothalamus**
brain structure important for motivation and control of the endocrine system.

hypothesis

a general statement about the way variables relate that is objectively falsifiable.

hypothetico-deductive reasoning
process of modern science where scientists begin with an educated guess, perhaps based on previous research, about how the world works, and then set about designing small controlled observations to support or invalidate that hypothesis.

I

id
according to psychoanalytic theory, the personality element representing basic instinctual drives, such as those related to eating, sleeping, sex, and comfort.

immune system
the body's system of organs, tissues, and cells that identify and destroy foreign invaders, such as bacteria and viruses, as well as cancer cells.

implicit attitude an attitude of which the person is unaware. **implicit learning**
the acquisition of information without awareness. **implicit memory**
memory that a person is not consciously aware of, such as learned motor behaviours, skills, and habits.

incentives external motives that indirectly indicate reward. **independent variable**
condition or event that is thought to be a factor in changing another condition or event.

individualistic
a culture that places the wants or desires of the person over the needs of the group.

individual therapy
psychotherapy format in which the therapist sees the client alone; the oldest of the modern formats.

inductive reasoning
reasoning process proceeding from small specific situations to more general truths.

information processing
the means by which information is stored and operates internally. **information-processing model**
view of memory suggesting that information moves among three memory stores during encoding, storage, and retrieval.

information-processing theory
a developmental theory focusing on how children learn, remember, organize, and use information from their environment.

information-processing theory
hypothesis that dreams are the mind's attempt to sort out and organize the day's experiences and to fix them in memory.

informed consent
what occurs when researchers give as much information as possible about the purpose, procedures, risks, and benefits of the study so that a participant can make an informed decision about whether or not to participate.

inoculation

exposing oneself to a relatively low level of stress in a controlled situation to improve later performance in a more stressful situation.

insight learning
a sudden realization of a solution to a problem or leap in understanding new concepts.

insomnia
sleep disorder characterized by a regular inability to fall asleep or stay asleep. **instincts**
inborn behavioural tendencies, activated by stimuli in our environments. **intellectual disability**
term describing individuals who display general intellectual functioning that is well below average and, at the same time, poor adaptive behaviour.

intelligence quotient (IQ)
Terman's measure of intelligence; the ratio of a child's mental age to her chronological age, multiplied by 100.

intelligence
the ability to learn, to meet the demands of the environment effectively, and to understand and control one's mental activities.

interactionism
a view emphasizing the relationship between a person's underlying personality traits and the reinforcing aspects of the situations in which they choose to put themselves.

interference theory
theory that forgetting is influenced by what happens to people before or after they take information in.

intermittent or partial reinforcement
a schedule of reinforcement where the behaviour is followed by reinforcement only some of the time.

International Classification of Diseases (ICD)
the system used by most countries to classify psychological disorders; published by the World Health Organization and currently in its 11th edition (ICD-10).

interneurons
neurons that typically have a short axon and serve as a relay between different classes of neurons; in the spinal cord, interneurons communicate with both sensory and motor neurons.

interpersonal circle
a two-dimensional personality trait model based on blends of dominance and nurturance.

intrinsic motivation
engaging in a behaviour simply for the satisfaction that is part of doing it. **introspection**
a method of psychological study involving careful evaluation of mental processes and how simple thoughts expand into complex ideas.

ion channels
pores in the cell membrane that can open and close to allow certain ions into and out of the cell.

J

James-Lange theory of emotion
a theory proposing that felt emotions result from physiological changes, rather than being their cause.

L

language a set of symbols used to communicate. **language comprehension**
the process of understanding spoken, written, or signed language. **language production** the structured and conventional expression of thoughts through words.

latent learning
a form of learning that is not expressed until there is a reward or incentive. **lateral hypothalamus (LH)**
a region of the hypothalamus important in signalling thirst and hunger. **law of effect**
a law that states that behaviours leading to rewards are more likely to occur again, while behaviours producing unpleasantness are less likely to occur again.

learned helplessness
a situation in which repeated exposure to inescapable punishment eventually produces a failure to make escape attempts.

learning a lasting change caused by experience. **leptin**
a protein produced by fat cells that is important for regulating the amount of food eaten over long periods of time.

lexical hypothesis
the idea that our language contains the important ways in which people can differ.

lexical meaning dictionary meaning of a word. **life changes**
shifts in life circumstances that require adjustment of some kind. **limbic system**
a group of interconnected brain structures that are associated with learning, memory, basic emotions, and drives.

linguistic relativity hypothesis
hypothesis suggesting that the vocabulary available for objects or concepts in a language influences how speakers of that language think about them.

lobotomy
surgical practice of cutting the connections between the frontal lobe and the lower centres of the brain.

longitudinal design
a research approach that follows the same people over a period of time by administering the same tasks or questionnaires and seeing how their responses change.

long-term memory
the memory system in which we hold all of the information we have previously gathered, available for retrieval and use in a new situation or task.

long-term potentiation (LTP)

a phenomenon where repeated stimulation of certain nerve cells in the brain greatly increases the likelihood that the cells will respond strongly to future stimulation.

loose associations or derailment
a common thought disorder of schizophrenia, characterized by rapid shifts from one topic to another.

loss aversion
a tendency to be motivated more strongly to avoid a loss rather than to achieve a gain, even if the potential loss and gain are of equal size.

lucid dreams
dreams in which sleepers fully recognize that they are dreaming, and occasionally actively guide the outcome of the dream.

lymphocytes
white blood cells that circulate through the body and destroy foreign invaders and cancer cells; important components of the immune system.

M

major depressive disorder
a disorder characterized by a depressed mood that is significantly disabling and is not caused by such factors as drugs or a general medical condition.

mania a persistent state of euphoria or frenzied energy. **mathematics disorder**
a deficit in mathematical ability, including the ability to do calculations, as well as the ability to understand mathematical word problems and mathematical concepts.

maturation the unfolding of development in a particular sequence and time frame.

mean arithmetic average of a set of scores. **mean**
the average score in a distribution. **median**
the score exactly in the middle of a distribution. **meditation**
technique designed to turn one's consciousness away from the outer world toward one's inner cues and awareness.

medulla
the part of the brain that controls basic bodily processes and regulates certain reflexes.

Meissner's corpuscles
sensory receptors that convert physical stimuli about sensory touch on the fingertips, lips, and palms.

memory the faculty for recalling past events and past learning. **memory consolidation**
process by which memories stabilize in the brain. **memory span**
maximum number of items that can be recalled in the correct order. **menopause**
series of changes in hormonal function occurring in women during their 50s, which lead to the end of the menstrual cycle and reproductive capabilities.

mental age
the intellectual age at which a person is functioning, as opposed to chronological age.

mental imagery picturing things in your mind. **mental processes**

activities of our brain when engaged in thinking, observing the environment, and using language.

mental set tendency to use problem-solving strategies that have worked in the past.

Merkel's discs
sensory receptors that convert information about light to moderate pressure on the skin.

metacognition the ability to understand and control one's mental activities.

metacognition thinking about one's own thoughts. **mirror neurons**
neurons fired when an animal or human performs an action or when they see another animal perform the same action.

miscarriage
discharge of the fetus from the uterus before it is able to function on its own.

mnemonic devices
techniques used to enhance the meaningfulness of information as a way of making them more memorable.

modelling what occurs when an observer learns from the behaviour of another. **mode**
the score that occurs most frequently in a distribution. **monocular cues**
visual clues about depth and distance that can be perceived using information from only one eye.

mood stabilizing drugs
psychotropic drugs that help stabilize the moods of people suffering from bipolar disorder.

morpheme the smallest units of a language that convey meaning. **motivation**
any internal process or condition that directs behaviour. **motive** a need or desire.

motor skills the ability to control bodily movements. **multifinality**
the idea that children can start from the same point and wind up at any number of different outcomes.

myelin
a fatty, white substance formed from glial cells that insulates the axons of many neurons.

myelination
development of fatty deposits on neurons that allow electric impulses to pass through neurons more efficiently.

N

narcolepsy sleep disorder marked by uncontrollable urge to fall asleep. **naturalistic observation**
study in which researchers directly observe people in a study behaving as they normally do.

natural reflex
an automatic involuntary response that typically occurs without learning. **negative**

correlation
relationship in which, on average, scores on one variable increase as scores on another variable decrease.

negative punishment
removal of a pleasant stimulus as a consequence of a behaviour to decrease the probability of the behaviour being repeated.

negative reinforcement
removal of an unpleasant stimulus after a response to increase the probability that the behaviour will reoccur.

negative symptoms
in the case of schizophrenia, symptoms that seem to reflect pathological deficits, including poverty of speech, flat affect, loss of volition, and social withdrawal.

nerve conduction velocity (NCV)
the speed with which electrical impulses are transmitted along nerve fibres and across synapses.

neural efficiency hypothesis
the hypothesis that bright individuals show lower brain activity than less bright individuals during tests of low to moderate cognitive difficulty.

neurofibrillary tangles
twisted protein fibres found within the cells of the hippocampus and certain other brain areas.

neuroimaging
techniques that allow for studying brain activity and structure by obtaining visual images in awake humans.

neuron a nerve cell. **neuroplasticity**
the brain's ability to create new neural pathways as a result of experience or following an injury.

neuroscience the study of the brain and the nervous system. **neurosis**
an abnormal behaviour pattern caused by unresolved conflicts between the id, ego, and superego.

neurotransmitter receptors
proteins in the membranes of neurons that bind to neurotransmitters.

neurotransmitters
specialized chemicals that travel across synapses to allow communication between neurons.

non-associative learning
learning that does not involve forming associations between stimuli. **non-REM sleep (NREM)** Stages 1 through 4 of normal sleep pattern. **non-verbal communication**
body language. **norepinephrine**
a neurotransmitter that is important for arousal and attention. **normal distribution**
a symmetrical, bell-shaped distribution in which most scores are in the middle, with smaller groups of equal size at either end.

norms social rules about how members of a society are expected to act. **nucleus accumbens** a brain area important for motivation and reward.

O

obedience the act of following direct commands, usually given by an authority figure.

obesity overweight characterized as a body mass index of over 30. **object permanence**
an infant's realization that objects continue to exist even when they are outside of immediate sensory awareness.

observational learning or social learning
learning that occurs without overt training in response to watching the behaviour of others, called models.

obsessions
persistent thoughts, ideas, impulses, or images that seem to invade a person's consciousness.

obsessive-compulsive disorder (OCD)
a mental disorder associated with abnormal anxiety-provoking thoughts that can lead to ritualistic behaviours.

obsessive-compulsive disorder (OCD)
a mental disorder associated with repeated, abnormal, anxiety-provoking thoughts and/or repeated rigid behaviours.

occipital lobe
lobe of the cortex at the back of the skull, important for processing very visual information.

odorants airborne chemicals that are detected as odours. **olfactory bulb**
the first region where olfactory information reaches the brain on its way from the nose.

olfactory receptor neurons
sensory receptor cells that convert chemical signals from odorants into neural impulses that travel to the brain.

olfactory sense our sense of smell. **operant or instrumental conditioning**
a form of associative learning whereby behaviour is modified depending on its consequences.

operationalize to develop a working definition of a variable that allows you to test it.

operations
Piagetian description of children's ability to hold an idea in their mind and mentally manipulate it.

opioids class of drugs derived from the sap of the opium poppy. **optic nerve**
the bundle of axons of ganglion cells that carries visual information from the eye to the brain.

ossicles
tiny bones in the ear called the maleus (*hammer*), incus (*anvil*), and stapes (*stirrup*).

oval window

a membrane separating the ossicles and the inner ear, deflection of which causes a wave to form in the cochlea.

overregularization
the process by which elementary school children over-apply newly-learned grammatical rules to improperly "correct" an irregular part of speech, such as a verb (e.g., "goed" instead of "went").

P

Pacinian corpuscles sensory receptors that respond to vibrations and heavy pressure.

panic attacks periodic, short bouts of panic. **panic disorder**
an anxiety disorder characterized by recurrent and unpredictable panic attacks that occur without apparent provocation.

papillae bumps on the tongue that contain clumps of taste buds. **parallel distributed-processing (PDP) (or connectionist) model**
theory of memory suggesting that information is represented in the brain as a pattern of activation across entire neural networks.

parasympathetic nervous system
the part of the autonomic nervous system that is active during restful times. **parietal lobe**
lobe of the cortex involved in processing information related to touch and complex visual information, particularly about locations.

perception the conscious recognition and identification of a sensory stimulus.

perceptual constancies
our top-down tendency to view objects as unchanging, despite shifts in the environmental stimuli we receive.

perceptual set readiness to interpret a certain stimulus in a certain way. **perfect correlation**
one in which two variables are exactly related, such that low, medium, and high scores on both variables are always exactly related.

personality disorder
an inflexible pattern of inner experience and outward behaviour that causes distress or difficulty with daily functioning.

personality inventory
a questionnaire designed to assess various aspects of personality. **personality**
the unique characteristics that account for enduring patterns of inner experience and outward behaviour.

personality trait model a mini-theory about the structure of personality traits.

personality traits
tendencies to behave in certain ways that remain relatively constant across situations.

phenotype the observable manifestation of a person's genetic inheritance. **phobia**
a persistent and unreasonable fear of a particular object, activity, or situation.

phoneme
the smallest unit of sound in a language; an individual sound such as ba, da, or ta.

phonology
the study of how individual sounds or phonemes are used to produce language.

photoreceptors the sensory receptor cells for vision, located in the retina. **phrenology**
a method of assessing a person's mental and moral qualities by studying the shape of the person's skull.

phylogeny the development of unique species over time. **pituitary gland**
brain structure that plays a central role in controlling the endocrine system. **placebo**
an inactive substance, such as a sugar pill or distilled water, that mimics a drug but has no active ingredients.

placenta a nutrient-rich structure that serves to feed the developing fetus. **polygenic trait** a trait that manifests as the result of the contributions of multiple genes. **pons**
uppermost or anterior (front) part of the brainstem that includes the locus coeruleus.

positive correlation
relationship in which, on average, scores on two variables increase together. **positive psychology**
an area of psychology focusing on positive experiences and healthy mental functioning.

positive punishment
presentation of an unpleasant consequence following a specific behaviour to decrease the probability of the behaviour being repeated.

positive reinforcement
presentation of a pleasant consequence following a behaviour to increase the probability that the behaviour will reoccur.

positive symptoms
in the case of schizophrenia, symptoms that seem to represent pathological excesses in behaviour, including delusions, disorganized thinking and speech, hallucinations, and inappropriate affect.

postsynaptic potentials
electrical events in postsynaptic neurons that occur when a neurotransmitter binds to one of its receptors.

posttraumatic stress disorder (PTSD)
an anxiety disorder experienced in response to a major traumatic event, characterized by lingering, persistent, frightening thoughts or memories of the traumatic events, along with anxiety, depression, and other symptoms.

posttraumatic stress disorder (PTSD)
an anxiety disorder in which fear and related symptoms continue to be experienced long after a traumatic event.

potentiation synchronous networks of cells firing together. **pragmatics**
the practical aspects of language usage, including speech pace, gesturing, and body language.

preconsciousness
level of awareness in which information can become readily available to consciousness if necessary.

predictive validity
the extent to which scores on a particular test successfully predict future performance on a measure related to the test.

prefrontal cortex
important brain structure located just behind the forehead and implicated in working memory.

prefrontal lobe
portion of the frontal cortex involved in higher-order thinking, such as memory, moral reasoning, and planning.

prejudice
negative and unjust feelings about individuals based on their inclusion in a particular group.

prenatal period the period of development from conception to birth. **preoperational stage**
according to Piaget, a developmental stage during which children begin to develop ideas of objects in the external world and the ability to work with them in their mind.

pressure an expectation or demand that someone act in a certain way. **primary appraisal**
appraisal of a stressor to determine how severe it is; the first stage in Richard Lazarus's description of how people experience stress.

primary mental abilities
seven distinct mental abilities identified by Thurstone as the basic components of intelligence.

primary punisher a stimulus that is naturally aversive to an organism. **primary reinforcer** a stimulus that has survival value and is therefore intrinsically rewarding.

primary sex characteristics
changes in body structure that occur during puberty that have to do specifically with the reproductive system, including the growth of the testes and the ovaries.

priming
activation of one piece of information, which in turn leads to activation of another piece, and ultimately to the retrieval of a specific memory.

proactive interference
competing information that is learned before the forgotten material, preventing its subsequent recall.

problem-focused coping
coping strategies focused on dealing directly with the stressor, such as by changing the stressor in some way.

problem solving determining how to reach a goal. **projective test**

a personality assessment device intended to tap a person's unconscious by presenting the person with an ambiguous stimulus and asking the person to interpret what the stimulus means.

prospective memory ability to remember content in the future. **proximodistal pattern**

a pattern in which growth and development proceed from the centre to the extremities.

psychoactive drugs

chemicals that affect awareness, behaviour, sensation, perception, or mood.

psychoanalytic theory

psychological theory that human mental processes are influenced by the competition between unconscious forces to come into awareness.

psychology the study of mental processes and behaviours. **psychometric approach**

an approach to defining intelligence that attempts to measure intelligence with carefully constructed psychological tests.

psychoneuroimmunology

an area of study focusing on links between stress, the immune system, and health.

psychosexual stages

according to psychoanalytic theory, stages in the development of personality; the stages —labelled oral, anal, phallic, latency, and genital—are primarily influenced by sexuality and aggression.

psychosis loss of contact with reality. **psychosurgery**

brain surgery often used in hopes of relieving abnormal functioning. **psychotherapy**

a treatment system in which a client and therapist use words and acts to overcome the client's psychological difficulties.

psychotropic drugs medications that act primarily on the brain. **puberty**

development of full sexual maturity during adolescence. **punishment**

an experience that produces a decrease in a particular behaviour.

R

random selection

identifying a sample in such a way that everyone in the population of interest has an equal chance of being involved in the study.

rapid eye movement sleep (REM)

stage of sleep associated with rapid and jagged brainwave patterns, increased heart rate, rapid and irregular breathing, rapid eye movements, and dreaming.

rational-emotive behavioural therapy

Ellis's therapy technique designed to help clients discover and change the irrational assumptions that govern their emotions, behaviours, and thinking.

reading disorder

a deficit in reading comprehension, written spelling, and word recognition. **recall tasks**

memory tasks in which people are asked to produce information using no or few retrieval cues.

recessive trait
a trait that is only expressed if a person carries the same two genetic alleles (e.g., is homozygous for the trait).

reciprocal socialization the transactional relationship between parent and child.

recognition tasks
memory tasks in which people are asked to identify whether or not they have seen a particular item before.

reflexes
programmed physical reactions to certain cues that do not require any conscious thought to perform.

rehearsal
conscious repetition of information in an attempt to make sure the information is encoded.

reinforcement
a learning process that increases the likelihood a given response will be repeated.

reinforcer an experience that produces an increase in a certain behaviour. **relational psychoanalytic therapy**
a school of psychodynamic therapy holding that therapists should work to form more equal relationships with clients.

relative refractory period
a brief period just after the absolute refractory period during which a neuron can fire only if it receives a stimulus stronger than its usual threshold level.

reliability the degree to which a test produces the same scores over time. **replication**
repeated testing of a hypothesis to ensure that the results you achieve in one experiment are not due to chance.

representations
what results when a person has the ability to understand symbols (such as words) and to think about objects and events as mental entities.

representativeness heuristic
the assumption that individuals share characteristics of the category of which they are a member.

repression
the most basic defence mechanism; the process of keeping unpleasant memories or thoughts buried deep within the unconscious mind.

research ethics board (REB)
research oversight group that evaluates research to protect the rights of participants in the study.

resilience
the ability to recover from or avoid the serious effects of negative circumstances.

resistance

practice in which clients encounter a block in their free associations or change the subject to avoid a potentially painful discussion.

response the way we react to stimuli. **resting potential**

the electrical charge of a neuron when it is at rest. **restorative theory of sleep**

theory that we sleep to allow the brain and body to restore certain depleted chemical resources and eliminate chemical wastes that have accumulated during the waking day.

reticular formation

a complex neural network extending from the hindbrain into the midbrain that plays a central role in regulating consciousness and arousal.

retina

a specialized sheet of nerve cells in the back of the eye containing the sensory receptors for vision.

retinal disparity the slight difference in images processed by the retinas of each eye.

retrieval

a basic activity of memory, involving recovery of information when we need it later.

retrieval cues

words, sights, or other stimuli that remind us of the information we need to retrieve from our memory.

retroactive interference

learning of new information that disrupts access to previously recalled information.

retrograde amnesia

inability to remember things that occurred before an organic event. **retrospective memory** ability to remember content from the past. **reward-deficiency syndrome**

theory that people might abuse drugs because their reward centre is not readily activated by usual life events.

reward learning pathway

brain circuitry that is important for learning about rewarding stimuli. **risk factors**

biological and environmental factors that contribute to problem outcomes. **rods**

photoreceptors most responsive to levels of light and dark. **Ruffini's end-organs**

sensory receptors that respond to heavy pressure and joint movement.

S

sample

the group of people studied in an experiment, used to stand in for an entire group of people.

scaffolding

developmental adjustments that adults make to give children the help that they need, but not so much that they fail to move forward.

Schachter and Singer's two-factor theory of emotion

a theory proposing that an emotional state is a function of both physiological arousal and cognition.

schemas
knowledge bases that we develop based on prior exposure to similar experiences or other knowledge bases.

scheme
Piaget's proposed mental structures or frameworks for understanding or thinking about the world.

schizophrenia
a mental disorder characterized by disorganized thoughts, lack of contact with reality, and sometimes auditory hallucinations.

schizophrenia
a mental disorder characterized by disorganized thoughts, lack of contact with reality, and sometimes hallucinations.

secondary appraisal
appraisal of one's personal resources and ability to cope with a stressor; the second stage in Richard Lazarus's description of how people experience stress.

secondary punisher
a stimulus that becomes aversive when associated with a primary punisher. **secondary reinforcer**
a neutral stimulus that becomes rewarding when associated with a primary reinforcer.

secondary sex characteristics
changes that occur during puberty and that differ according to gender, but aren't directly related to sex.

sedative-hypnotic drugs
class of drugs that produces feelings of relaxation and drowsiness. **self-actualization**
the need of humans to fulfill their full and special potential; the highest level of need in Maslow's hierarchy of needs.

self-concept
a pattern of self-perception that remains consistent over time and can be used to characterize an individual.

self-determination
instinctive feelings of competence, relatedness, and autonomy that give purpose to life.

self-help groups
groups consisting of people who have similar problems and come together to help and support one another without the direct leadership of a professional clinician.

self-perception theory
a theory suggesting that when people are uncertain of their attitudes, they infer what the attitudes are by observing their own behaviour.

self-serving bias
the tendency people have to attribute their successes to internal causes and their failures to external ones.

semantic code

cognitive representation of information or an event based on the meaning of the information.

semantic memory a person's memory of general knowledge of the world. **semantics** the study of how meaning in language is constructed of individual words and sentences.

senile plaques
sphere-shaped deposits of a protein known as beta-amyloid that form in the spaces between cells in the hippocampus, cerebral cortex, and certain other brain regions, as well as in some nearby blood vessels.

sensation the act of using our sensory systems to detect environmental stimuli.

sensitive period
a point in development during which the brain is more *susceptible* to influences.

sensitization
a form of non-associative learning whereby a strong stimulus results in an exaggerated response to the subsequent presentation of weaker stimuli.

sensory adaptation
the process whereby repeated stimulation of a sensory cell leads to a reduced response.

sensory memory
memory involving a detailed, brief sensory image or sound retained for a brief period of time.

sensory receptor cells
specialized cells that convert a specific form of environmental stimuli into neural impulses.

sensory transduction
the process of converting a specific form of environmental stimuli into neural impulses.

***s* factor**
a theoretical specific factor uniquely tied to a distinct mental ability or area of functioning; part of Spearman's two-factor theory of intelligence.

shaping
introducing new behaviour by reinforcing close approximations of the desired behaviour.

signal detection theory
Theory that the response to a signal in every situation depends on an individual's ability to differentiate between the signal and noise, and on their response criteria.

sleep apnea
sleep disorder characterized by repeatedly ceasing to breathe during the night, depriving the brain of oxygen and leading to frequent awakenings.

sleep spindles
bursts of brain activity lasting a second or two; occur during Stage 2 sleep. **social anxiety disorder**
an anxiety disorder in which people feel severe, persistent, and irrational fears of social or performance situations in which embarrassment may occur.

social cognition

the way in which people perceive and interpret themselves and others in their social world.

social facilitation an effect in which the presence of others enhances performance.

social identity theory
a theory that emphasizes social cognitive factors in the onset of prejudice. **social loafing**
a phenomenon in which people exert less effort on a collective task than they would on a comparable individual task; also known as free riding.

socially desirable responding
tailoring answers on personality inventories to try to create a good impression. **social neuroscience** the study of social functioning and how it is tied to brain activity. **social psychology**
an area of psychology that seeks to understand, explain, and predict how people's thoughts, feelings, and behaviours are influenced by the actual, imagined, or implied presence of others.

social role
a set of norms ascribed to a person's social position—expectations and duties associated with the individual's position in the family, at work, in the community, and in other settings.

social role theory
theory that gender differences occur because girls and boys develop different behaviours and skills based largely on differences in gender role expectations.

social skills training
behavioural therapy technique in which therapists serve as models and teachers to help clients acquire desired social behaviours.

sociobiologists
theorists who believe humans have a genetically innate concept of how social behaviour should be organized.

sodium-potassium pump
protein molecules in the membrane of cells that push out sodium ions and push in potassium ions.

somatic nervous system
all the peripheral nerves that transmit information about body sensation and movement to and from the central nervous system.

somatic symptom and related disorders
excessive thought, feelings, and behaviours related to somatic symptoms.

somatosensory strip
an area of the parietal cortex that processes tactile information coming from our body parts.

sound waves vibrations of the air in the frequency of hearing. **source misattribution**
remembering information, but not the source it came from; can lead to remembering information from unreliable sources as true.

spaced practice effect
facilitated encoding of material through rehearsal situations spread out over time.

spatial navigation learning
learning that involves forming associations among stimuli relevant to navigating in space.

specific learning disorder
a disorder that interferes with the acquisition and use of one or more of the basic psychological processes involved in the development of academic skills: oral language, reading, written language, and mathematics.

speech the expression of language through sounds. **spinal cord**
portion of the central nervous system that extends down from the base of the brain and mediates sensory and motor information.

spontaneous recovery
re-emergence of a conditioned response sometime after extinction has occurred. **stage**
a distinct developmental phase in which organisms behave, think, or respond in a particular way that is qualitatively different from the way they responded before.

standard deviation statistical index of how much scores vary within a group.

standardization the use of uniform procedures in administering and scoring a test.

state-dependent memory
memory retrieval facilitated by being in the same state of mind in which you encoded the memory in the first place.

states of consciousness
the level of awareness we have of our external surroundings and internal states.

stereotypes
fixed overgeneralized and oversimplified beliefs about a person or a group of people based on assumptions about the group.

stereotype vulnerability or threat
a phenomenon in which people in a particular group perform poorly because they fear that their performance will conform to a negative stereotype associated with that group.

stimulants substances that increase the activity of the central nervous system. **stimuli**
elements of the environment that trigger changes in our internal or external states.

stimulus discrimination
what occurs when an organism learns to emit a specific behaviour in the presence of a conditioned stimulus, but not in the presence of stimuli similar to the conditioned stimulus.

stimulus generalization
what occurs when stimuli similar to the original conditioned stimulus trigger the same conditioned response.

storage a basic activity of memory, involving retention of information for later use.

stressor a situation or circumstance that triggers the stress response. **stress**

state brought on by any situation that threatens or appears to threaten a person's sense of well-being, thus challenging the individual's ability to cope.

structuralism
a philosophical approach that studies the structure of conscious experience.

substantia nigra a brain region important in fluidity of movement and inhibiting movements.

superego
according to psychoanalytic theory, the personality element in charge of determining which impulses are acceptable to express openly and which are unacceptable; develops as we observe and internalize the behaviours of others in our culture.

superfactor
a fundamental dimension of personality made up of a related cluster of personality traits.

suprachiasmatic nucleus (SCN)
a small group of neurons in the hypothalamus responsible for coordinating the many rhythms of the body.

survey study in which researchers give participants a questionnaire or interview them.

sympathetic nervous system
the part of the autonomic nervous system that is activated under conditions of stress.

synapses
tiny spaces between the axon terminal of one neuron and the neuron through which chemical communication occurs.

synaptic pruning
developmental reduction of neuronal connections, allowing stronger connections to flourish.

synaptic vesicles
membrane-bound spheres in the axon terminals of neurons in which neurotransmitters are stored before their release.

syntax
the system for using words (semantics) and word order to conveymeaning (grammar).

systematic desensitization
a process used to condition extinction of phobias through gradual exposure to the feared object or situation.

T

taste buds
clusters of sensory receptor cells that convert chemical signals from food into neural impulses that travel to the brain.

telegraphic speech
speech that consists of minimalistic sentences; characterizes early toddlerhood and is the first evidence of sentence formation.

temperament

a biologically-based tendency to respond to certain situations in similar ways throughout a person's lifetime.

temporal lobe
part of the cortex important in processing sound, in speech comprehension, and in recognizing complex visual stimuli, such as faces.

teratogens any environmental agent that causes damage during gestation. **thalamus**
an area of the brain that serves, in part, as a relay station for incoming sensory information.

theories ideas about laws that govern phenomena. **theory of mind**
an awareness of one's own mental states and the mental states of others. **theory of multiple intelligences**
theory that there is no single, unified intelligence, but instead several independent intelligences arising from different portions of the brain.

therapy outcome studies research that looks at the effects of various treatments.

threshold
the point at which the magnitude or intensity of a stimulus initiates a neural impulse.

threshold
the point at which the relative influence of other neurons succeeds in causing a neuron to initiate an action potential.

token economy
operant conditioning therapy program in which participants receive tokens (that can be traded for rewards) when they display desired behaviours.

tolerance
mark of physical dependence on a drug, in which the person is required to take incrementally larger doses of the drug to achieve the same effect.

tonotopic map representation in the auditory cortex of different sound frequencies.

top-down processing
perception processes led by cognitive processes, such as memory or expectations.

transcranial magnetic stimulation (TMS)
a procedure in which an electromagnetic coil placed on or above a person's head sends a current into the prefrontal cortex; used to treat severe depression.

transduction
process that involves converting stimulus energy into neural impulses that can be interpreted by the brain.

transference
process through which clients come to act and feel toward the therapist as they did toward important figures in their childhood.

traumatic events unexpected events severe enough to create extreme disruptions.

treatment or therapy
systematic procedures designed to change abnormal behaviour into more normal behaviour.

trephining

prehistoric practice of chipping a hole in the skull as a treatment for various brain conditions.

triangular theory of love
a theory proposed by Robert Sternberg that love is composed of three elements: intimacy, passion, and commitment.

triarchic theory of intelligence
Sternberg's theory that intelligence is made up of three interacting components: internal, external, and experiential components.

tympanic membrane the ear drum. **Type A**
a personality type characterized by competitiveness, impatience, and anger and hostility.

Type B
a personality type that is less aggressive, more relaxed, and less hostile than Type A.

Type C
a personality type characterized by difficulty in expressing or acknowledging negative feelings.

Type D
a personality type characterized by negative affectivity such as worry or gloominess and social inhibition.

U

unconditional positive regard acceptance without terms or conditions.

unconditioned response (UR)
a physical response elicited by an unconditioned stimulus; it does not need to be learned.

unconditioned stimulus (US) a stimulus that on its own elicits a response.

unconscious
hypothesized repository of thoughts, feelings, and sensations outside human awareness, thought in some theories to have a strong bearing on human behaviour.

unconscious motivations
motivations that people are unaware of and cannot verbalize. **unconscious state**
state in which information is not easily accessible to conscious awareness.

V

vagus nerve stimulation
a procedure in which an implanted device sends electrical signals to the brain through the vagus nerve; used to treat severe depression.

validity coefficient
a correlation coefficient that measures validity by correlating a test score with some external criterion.

validity

the extent to which a test accurately measures or predicts what it is supposed to measure or predict.

variable condition, event, or situation that is studied in an experiment. **variable interval schedule**

a schedule of reinforcement that occurs after varying amounts of time. **variable ratio schedule**

a schedule of reinforcement that occurs when the number of responses required for reinforcement is unpredictable.

ventromedial region of the hypothalamus (VMH)

a region of the hypothalamus important in signalling satiety. **vicarious learning**

learning that occurs when an individual observes the consequences to another's actions and then chooses to duplicate the behaviour or refrain from doing so.

violation-of-expectation

an experimental approach capitalizing on infants' and toddlers' heightened reactions to an unexpected event.

voluntarism

a theory in which will is regarded as the ultimate agency in human behaviour; belief that much of behaviour is motivated and that attention is focused for an explicit purpose.

W

wear-and-tear theory theory suggesting we age because use of our body wears it out.

Wernicke's aphasia

a neurological condition associated with damage to Wernicke's area where a person cannot understand language.

Wernicke's area

a brain region located in the temporal lobe that is important for language comprehension.

Wernicke's area

an area of the temporal cortex important in helping us understand language.

withdrawal symptoms

unpleasant and sometimes dangerous side effects of reducing intake of a drug after a person has become addicted.

working memory a short-term memory store that can hold five to nine items at once.

Y

Yerkes-Dodson law

law stating that ideal performance on a task occurs when the arousal level is optimized to the difficulty level of the task.

Z

zone of proximal development

the gap between what a child could accomplish alone and what the child can accomplish with help from others.

zygote a single cell resulting from successful fertilization of the egg by sperm.

Subject Index

Note: Page references followed by “f” indicate content in figures; page references followed by “t” indicate content in tables.

A

ABC model of attitudes, 535

abnormal brain structures, 657

abnormal psychology, 620

see also psychological disorders

Aboriginal Head Start, 119–120

Aboriginal Head Start Association of British Columbia, 119

Aboriginal Head Start in Urban and Northern Communities (AHSUNC), 119

Aboriginal Head Start on Reserve (AHSOR), 119

Aboriginal people. *See* Indigenous experiences

absolute pitch, 187

absolute refractory period, 94

absolute threshold, 169, 170t

academic psychology, 22, 23

acceptance and commitment therapy, 696

accommodation, 136

accurate empathy, 697

acetylcholine, 95t, 96, 97, 332

acetylcholinesterase, 96

the Ache, 135

achievement, 460–462

acquired brain injury, 100

acquisition, 270f

acrophobia, 648t

ACTH. *See* adrenocorticotropic hormone (ACTH)

action potential, 86, 92–96, 92f, 93f, 173

activation-synthesis, 229f

activation-synthesis hypothesis, 228–229

activation-synthesis model, 228–229
active searching, 292
actor–observer effect, 548–549, 548f
acute pain, 184
acute stress disorder, 624t, 651
acute stressor, 580
Adam, Allan (Chief), 569
Adams, John Quincy, 622
adaptation, 15–17
adaptive, 9
adaptive theory of sleep, 222
addiction, 242, 243
addictive disorders, 624t
additive task, 561
Adler, Alfred, 496
adolescence, 151–159
    emotional development, 156–159
    growth spurt, 151–152, 152f
    identity development, 158
    moral development, 153–156
    physical development, 151–152
    social development, 156–159
adolescent egocentrism, 153
adrenal cortex, 591
adrenal glands, 151
adrenal medulla, 591
adrenocorticotropic hormone (ACTH), 591
adulthood, 159–163
    aging, 160, 161
    cognitive decline, slowing, 334
    cognitive development, 160–161
    emotional development, 161–162
    physical development, 160

social development, 161–162
advanced sleep phase syndrome, 234
advertising, 16
aerial perspective, 201
aerophobia, 648t
aesthesis, 167
affect program, 479
afferent neurons, 71
affiliation, 460
afterimage, 195, 195f
age of the Earth, 107
age of viability, 126–127
agentic characteristics, 553
ageusia, 176
aggression, 41–42, 287–288, 492, 569–570
see also violence
aging, 160, 161, 162–163, 334

archetypes, 496
Aristotle, 7–8, 8f, 171
Arnold, Magda, 26
arousal theory, 433–434
Asch studies, 555–556
assimilation, 136
association areas, 187
association cortex, 80
Associationism, 8
associative learning, 261, 264
astrocytic feet, 88
astroglia, 87–88
attachment, 145–148, 571–572
attachment styles, 147
attention, 213, 291–293
attention deficit hyperactivity disorder (ADHD), 263, 412
attitude specificity, 539
attitude strength, 539
attitudes, 535
    ABC model of attitudes, 535
    and behaviour, 539
    change in, 536–539
    cognitive dissonance theory, 537–538
    development, 535–536

implicit attitudes, 540–541
misrepresentation of, 539–541
persuasion, 545–547, 545f
prejudice, 542–545
self-perception theory, 538–539
social desirability factor, 540
stereotypes, 542–545
attraction, 570–572
attractiveness, 448
attributions, 547–551
atypical development
see also psychological disorders; *specific types of disorders*
learned helplessness, 285
teratogens, 128–129
auditory hallucinations, 655
auditory sense, 185–191
see also hearing
auras, 177
Authentic Happiness (Seligman), 37
authoritarian parenting styles, 149t
authoritative parenting styles, 149t
autism spectrum disorder (ASD), 263, 295, 623t
automatic behaviours, 218
automatic processing, 307–308, 367–368
automatic thoughts, 640
autonomic nervous system (ANS), 71, 464, 466t, 651
autonomic reactivity, 596
autonomy *versus* shame and doubt, 146, 158t
autopsy tissue, 65
availability heuristic, 372–373
aversion therapy, 690, 691, 691f
avoidance motivation, 457
avoidance–avoidance conflict, 582

avoidant attachment, 572
avoidant personality disorder, 528t, 623
avoidant/restrictive food intake disorder, 624t
avolition, 655
awake. *See* conscious awareness
awareness, 291–293
axon, 86, 86f
axon terminal, 86
